ON

DISINTEGRATION OF THE BLOOD.

By JAMES PAXTON, M.D., Rugby.

Read at the Anniversary Meeting at Hull, August 6th and 7th, 1850.

For some time past I have been engaged in observing, with considerable attention, the physical characteristics of the blood, in all those cases in my practice which afforded a fit opportunity for the examination. For this purpose, first, the specific gravity was ascertained; second, the relative quantity of serum and crassamentum was gauged, by means of a *hæmatometer*, (constructed on the plan of an *alkalimeter*.) This is a tube 6-8ths of an inch in diameter, marked at the height at which 1000 grains of distilled water would stand; it is then graduated by a scale of 100 degrees. Third, the quality of the serum was known by filling a smaller tube, to the line of 100 grains of distilled water. On taking the specific gravity we may judge of its density and the quantity of albumen it contains. No doubt better contrivances for the same end might be suggested; but though these instruments are simple, they are sufficient to give important indications of the qualities of the blood, and wherein there is a departure from a normal condition. To mention some select instances:—The blood of a man aged 61, of full habit of body, complaining of pain in the head, showed 91 per cent. of cruor. Let us contrast this with the blood in a case of chlorosis, in a girl of 17 years of age, who also was suffering from headache, in which the cruor was only 43 per cent. Blood taken in pleurisy, from a woman aged 39, contained 83 per cent. of cruor, 3 per cent. of fibrin in the form of inflammation and buff, and the remainder 14 per cent. of serous fluid. Without entering into details of the per centage of the physical elements of the blood under various diseases, and at the different periods of the disease, the experiments before us intimate that pathological hæmatology has just claims to our notice. Thus, from an examination of the blood in this manner, and seeing a deficiency in the normal gauge of the crassamentum, we may confidently assume there are deficient constitutional powers in the subject from which it was drawn. Moreover, these observations are of use to furnish us, at least, with general ideas of the morbid condition of the blood, with much more accuracy than is usually attempted. The number of inspections of blood in a defective state have led to the arrangement of a group of diseases which may be strictly referred to a disturbed state of the circulation, producing either a transposition or total rejection of some of the vital elements. The object of this paper is to submit to the Association illustrations, in several affections, under which this evidently occurs.

I am about to consider diseases attended by disruption of the composition of the blood, and the dispersion of some of its vital elements. Now, whether that portion which is separated remain in the system or is totally excluded, there are good reasons for supposing the origin of the disruption to be from a loss of vital affinity in the organisms. On the present occasion it is my intention to speak only of leading principles in a branch of hæmatology specially relating to privations of the blood. I have adopted the term *disintegration* as most expressive of a dissociation of a triple compound of serum, fibrin, and hæmatosin. During sound health these organic elements are retained in the vascular system. The chemical products, or some contingent or new forms of organic matter only, are excluded by means of the secretions. In fact, to have any of the organisms of the blood present themselves, ex-circulatory, is opposed to the laws of the integrity of the circulating fluid, and would at once induce suspicions of a disorganization in its composition. We might bring under review a large class of diseases which seem to originate in disturbances of the organic elements, but will confine our notice to those affections in which the vital forces expel some of these constituents. One of the most remarkable instances of this is the expulsion of serum in *morbus Brightii*. Here the blood becomes deprived of its serum; on the one hand, a part escapes into the cavities and the tissues of the body, while another part is removed by the agency of the kidneys; on the other hand, there are diseases in which the gastro-enteritic apparatus is employed in the performance of a similar task, viz., to deserumize the blood; as in diarrhœa and cholera, wherein a double process is effected—first, a portion of the blood is deserumized, and secondly, it is discharged from the constitution. In other instances the serum, after its exclusion from the vessels, is detained in close cavities in the pleura, the tunica vaginalis, or in cysts. In such situations it is liable to remain with great inconvenience to the functions of im-

portant viscera. When deposited in the areolar tissue of the limbs, I need not say that their mechanism is exceedingly impeded. This is a general view of that species of disintegration which is known by a loss of serum. Although the objection might be raised that these fluids are mere secretions or exhalations, this is altogether a verbal distinction, inasmuch as the blood is minus the quantity of albumen contained in the fluids just named. To confine myself to a limited exemplification of deserumization. It may be artificially induced by the application of a blister to the skin.

The poison of the cantharides inflicts an injury, which ends in an effusion of serum under the epidermis, the blood having been deprived of as much serum as is visible in the vesication. Superficial burns and scalds subject the locality to rapid withdrawal of serum. Certain topical injuries cause topical disintegration of the blood, and an effusion of serum. Obstructions in the veins invariably produce a disengagement of serum. Thus the pressure of the gravid uterus, or of pelvic tumours on the iliac veins, frequently occasions effusion in the lower extremities. In phlegmasia dolens, by an inflammation of the saphena and its branches, or of the femoral vein, the current of the blood being interrupted, exudations into the cellular tissue certainly follow. The fluids in œdema, hydrocephalus, hydrothorax, or of hydrocele, prove their identity with the serum of the blood, by the albumen which, more or less abundantly, they contain. The pathology of limited dropsy or abstractions of serum appears scarcely explicable without admitting a dissociation of the liquor sanguinis and the red corpuscles. In cachexia the vessels may be feeble, *per se*, and incapable of transmitting the blood unimpaired, yet in leuco-phlegmatic temperaments it is more than probable that effusions originate in excess of serosity, and the escape of serum tends to afford relief by restoring, in some measure, the hæmatic standard. This is illustrated in an early scrofulous diathesis, where, in childhood, there is a disposition in the cerebral circulation to part with serum. The fluid which distends the ventricles of the brain contains albumen. Serous apoplexies likewise are of this character, notwithstanding the attack may arise from detention of blood in the sinuses, owing to disease of the heart. Taking into account the composition of the fluid in partial dropsy, and calculating the amount of albumen detected in it, we may conclude there must be partial disintegration of the blood. Nevertheless, structural and functional derangements of the vessels, as well as their contents, may be involved in local dropsy. Hence mechanical causes, or a ligature on the femoral artery, will occasion a temporary œdematous tumefaction, in consequence of an interruption to the current of the circulation. One of the results of an impediment in the portal system is a collection of serum in some part of the body. Instances of limited disintegration of the blood could easily be multiplied, but I will only mention its manifestation in œdema of the arm, when the axillary glands are implicated.

Limited collections of serum constitute the first series of disintegrations of the blood. The second series shows an unlimited serous effusion; its remote cause is more obscure than the former, and it is by a combination of circumstances that its integrity is not maintained. Anasarca is one of the effects of a slow process of general disintegration of the blood, and general exudation of the liquor sanguinis and colourless corpuscles. Already an example of this form of deprivation of serosity has been referred to in albuminuria, where there is an excessive tendency of the serum to separate from the mass of the circulation. During the progress of this disease the liquor sanguinis is continually escaping by the kidneys, or is infiltrating into the areolar tissue, and perhaps finds its way into the pleura or peritoneum. Under these circumstances it has been ascertained that the relative proportion of corpuscles no longer continues. In one case the hæmatometer indicated 47 per cent. of serum, with a specific gravity of 1015, the healthy standard being 1030. To explain this circumstance I found, at the commencement of the complaint, the urine contained so large a quantity of serum, that when heated it was completely solid. The development of albuminuria is discovered by the unceasing circulation of the vital energies to exclude a quantity of serum from the vascular canals. Pathologists have apprehended a mutilated state of the blood; if so, it is desirable to define that state with as much precision of ideas as science will warrant. Dr. Johnson, of King's College, very properly considers that the existence of albumen in the urine is due to a disturbance in the circulation.* Dr. Ranking, with his usual clearness of judgment, after a comprehensive review of the various publications on Bright's disease, arrives at the following conclusion, that "there are diseases which attack the liver, spleen, and kidneys, which depend on an abnormal condition of the blood."† All the changes described so accurately by microscopists as taking place in the interstitial structure of the tubuli of the kidney are purely accidental, and altogether the result of "albuminous dyscrasy," induced by intemperate habits, unhealthy residence, or modes antihygienic. The tendency of the serum to become excirculatory can the more readily be accounted for by supposing that incidental circumstances have contributed to a loss of cohesion dependent on a loss of vital affinity in the sanguineous elements. While the blood preserves a perfectly healthy condition, its organic principles are inseparably retained within the boundaries of the circulatory system. There is no exception to this law. When, however, the renal organs, whose office is solely to secrete and convey the chemical material, is compelled to assume a new office, and convey a physical material of the blood, and when also we detect the latter in remote and foreign situations of the body, we may expect to find a corresponding deficiency in the circulation. As we find a low specific gravity of serum in albuminuria, so we ought to feel no difficulty in believing what some of the most en-

* *Medical Gazette*, November, 1845.

† Transactions of the Provincial Medical and Surgical Association, 1847.

lightened pathologists have conjectured, that this affection is essentially a disease of the blood. It does not appear that the kidneys are anything more than mere agents in the removal of albumen, and in the performance of that duty sustain damage from retention of fibrin and fat globules; indeed, the quantity of the urine is seldom to be attributed to an error of these organs, but is rather to be imputed to a disturbed state of organic principles in other places. The granular degeneracy is entirely the result of protracted serous disease. Dr. Prout, in his Gulstonian lecture at the College of Physicians, exhibited the kidneys of a patient of Dr. Rowe's, who died of albuminuria, which were perfectly free from disease.* They transmitted serum without injury to their capacity or structure. Albuminuria consequently arises from a lesion of the blood, capable of demonstration. There are a variety of causes, particularly in large cities, which are calculated to impair the sound state of the blood. Dr. Bright instituted a series of experiments by taking the patients promiscuously as they lay in the wards of the hospital. The whole number amounted to 130, out of which he found no less than eighteen to have coagulable urine.† I am in the daily habit of testing the urine, but I confess I do not find albumen of so frequent occurrence. In rural districts, among an agricultural population, the condition of the blood is less deteriorated. Dr. Owen Rees and others have detected albumen in the urine of persons dying from complaints quite unconnected with lesions of the kidneys. He judiciously observes, that, "it is not right to lay much stress on albumen in the urine as indicative of nephritic disease."‡ The term albuminaria would be equally applicable to every species of disorder in which there is an adventitious collection of serous fluid; it might be applied to all the diseases in the order *Aquosæ* of Cullen. Every species of dropsy, as it regards the proximate cause, belongs to this series of disintegration—namely, deserumized blood. Sometimes there may be a drain of serum through the renal organs, at other times the serum is detained in certain parts of the system; be this as it may, the discovery of serum ex-circulatory would always lead to the inference of abstraction from the blood. In cases of Bright's disease we actually detect a deficiency in almost every analysis. On the contrary, an excess of serum, as in anæmia, may probably act in the same way in causing exosmose into the tissues in consequence of a dissolution of a portion of the triple organization of the blood.

The third series of disintegration consists in a deprivation of fibrin as well as serum. The most striking illustration occurs in malignant cholera. It is unnecessary to describe all the attendant phenomena, but to consider the hæmatology of this disease. After the reception of the choleraic poison, the abstraction of both serum and fibrin takes place frequently with such sudden and extraordinary violence, that during an attack from six to twenty-four pounds of sero-fibrous fluid is expelled by the action of the stomach and bowels, in the course of a few hours. Mr. Grainger, who devoted much time and attention to investigations of this disease on the continent and in this country, in his lecture at St Thomas's Hospital last year, describes cholera as an affection of the blood. "That the best results which have been attained by the German pathologists, particularly those of Berlin, is that the first impression is aerial, acting on the blood, and thus the blood became poisoned." Dr. Wells has expressed in a short sentence his opinion of the nature of cholera—"A loss of vitality of the blood." Both of these gentlemen approach the true theory. One would imagine it impossible to overlook the destruction of a large portion of the colourless corpuscles. The alvine discharges, consisting chiefly of serum and coagulated fibrin. During health these substances are held in solution, but the vital force being withdrawn the albumen coagulates, the fibrin is precipitated, and we behold these substances in curdled floculi, floating in the dejections. There is no one who has examined the blood in algide cholera who has not remarked its altered appearance. The dark colour and thick consistence have led some to compare it to tar, others to currant jelly. Dr. Parkes believes the fibrin loses its power of combination, and is poured into the intestines in floculi, known as the solid ingredient in the so-called rice-water evacuations. Much as we may regret that the remote source of this scourge of the nations is still a hidden mystery, the immediate is patent to our inspection. We perceive the analogy there is between the action of the choleraic poison on the system, and the operation of an over-dose of tartarized antimony or arsenious acid. Indeed there is so great a resemblance of symptoms attendant on poisoning with arsenic, that it has often been mistaken for an attack of cholera. A large portion of blood has been disentegrated; this is followed by uncommon efforts to expel the affected organisms, and the spasmodic action seldom ceases until the whole of the affected corpuscles escape from the circulation, unless in fatal cases, where the organs concerned in the disengagement of the poison at length are disabled and unequal to the task. If the transparent corpuscles are very partially invaded, by timely aid of medicine and *vis vitæ* of the constitution, a reaction may be established which may neutralize the choleraic virus. To use the words of an eminent Professor:—"There are instances of the operation of the vital actions accomplishing the expulsion of noxious matter, and of that part of the animal fluid which have been corrupted by it.* This appears to be the course and determination of cholera, at least under a mild form. The dead corpuscles are excluded from the mass of the circulation. The assimilative process makes up the deficiency and restores the healthy tone of the blood.

It is not intended at this time to present tables of analysis; it will answer the purpose of the argument,

* 1831.

in support of the theory advanced, to state that the blood of a healthy person contains of solid residue, on an average, 210 parts per 1000; but when an attack of Asiatic cholera has abstracted the transparent corpuscles, fibrin, and liquor sanguinis, the solid residuum amounts to 360 parts per 1000. In hæmatological inquiries there will be great irregularities in the results. The relative proportions of the organic principles are not so much dependent on age or sex as on habits of body and modes of life.

A fourth series of disintegrations of the blood is apparent in the separation and deposit of its fibrin. There is a frightful epidemic, well known in the West India islands, in which the fibrin becomes ex-circulatory, and eventually undergoes a slow condensation, and, as in all fibrinous deposits, it is then rendered insoluble. Such is elephantiasis. The parts most frequently affected are the lower extremities, but immense collections may be situated in the loose cellular tissue of the scrotum, or accumulated in the subcutaneous tissue of other parts. There is a class of tumours also with which we are more familiar, not only occupying the exterior of the body but invading the interior likewise; the morbid anatomy of which shews them to consist principally of condensed fibrin. The several stages of production are extravasation of serum, the aqueous portion of which evaporates by perspiration and exhalation from the lungs, leaving the insoluble fibrin under various forms. It has been demonstrated as intersecting scirrhous formations, and in such monstrous scrotal and preputial enlargements as such cases as *Hoc-loo's*, which are largely made up of fibrin, thrown out of the circulatory mass. The accretions distinguished as scirrhous, affecting the pylorus, the rectum, and the mamma, are of the same character. All these diseases are mainly composed of fibrinous exudations, in combination with, or existing as, a web containing other substances, as fat globules, cancer cells, and albuminous fluid. When fibrin is pure it often forms pseudo-membranes; as, for instance, in the adhesions of the pulmonary with the costal pleura, after a bad attack of pleuro-pneumonia. Inflammation induces a separation of fibrin; hence during inflammatory action fibrin is frequently poured into the canals lined with mucous membranes, as in croup, and in this specimen, where we have casts of the primary bronchiæ, produced by a transit of fibrin in acute bronchitis. The whole of this series are attributable to sanguineous derivations in consequence of an impaired vitalism of the blood, allowing of the exit of the liquor sanguinis by exosmose, or it may be ejected, under certain circumstances, by the energies of the animal powers. Fibrin while circulating in the system is always in solution, but when removed by disease it becomes solid.

The fifth series of cases of disintegration of the blood comprehends those affections in which effusions of red corpuscles or pure hæmatin is one of the most conspicuous features, as in scorbutus, purpura, and the petechiæ and vibices of typhus. The predisposing causes and primary sources of scorbutus have been traced to insufficiency of some needful article of diet, especially if the privation is attended by mental anxiety and alarm. Of the proximate cause there is no question. We know the blood is dehæmatized when hæmatin has visibly escaped from the circulation; when there is a deprivation of 60 or 80 per 1000 of coloured corpuscles. The deficiency of fibrin, also, in most cases, has been noticed; hence Magendie called this disorder "Defibrination of the blood;" and truly the blood from the gums does not coagulate, for the crassamentum is loose and weak—"a semi-fluid of the consistence of syrup."

As, however, a similar defective condition of the blood is present in the advanced stages of fever, and in the phlegmasiæ, scurvy is better pathologically distinguished by the evident drainage of coloured corpuscles from the mucous membranes. We obtain the most correct diagnosis from the leading symptoms, viz., by the spontaneous appearance of hæmatosin. Looking at the multitude of facts which cases of scurvy present, can we reasonably doubt the breaking up of the fabric of the blood? The nature of the hæmorrhages which penetrate the mucous surfaces abundantly prove it.

Purpura hæmorrhagica bears a close analogy to scorbutus. The blood exhibits a loss of 10 to 20 per cent. of red corpuscles; but the extravasation of hæmatosin is sub-epidermic. The specific gravity of the blood is lowered from 20 to 40 per 1000. Each case may vary, yet the deficient quantity of hæmatosin is universal.

In further illustration of the doctrine of disintegration of the blood, instances might be cited of hæmorrhagic transpirations from the skin. Although such cases are of rare occurrence, there is on record one instance most impressive. There was one man who, under intense agony, sweat drops of blood. The physical possibility of sanguineous exudations of this kind, under extreme mental excitement, is confirmed by various writers. Blainville has given a case of bloody perspiration.* Another case is related in the Philosophical Transactions† of a child who bled from every part of the surface of the body. A similar hæmorrhage from the tongue, mouth, and scrotum is described by Mr. Amyot.‡ I might refer to Mr. Howard's "History of Foreign Prisons." "On visiting the prison at Avignon, (says this great philanthropist,) the gaoler told me that he had seen drops of blood mingled with the sweat on the breast of prisoners under torture."§ It would be subject for inquiry whether there are not numerous diseases in some of their stages attended with disintegration of the blood. Severe inflammation tends to isolate the colourless corpuscles, and in one patient terminates in effusion of serum, in another in deposition of fibrin. Dr. Alison infers "that inflammation and its effects are inexplicable by any alteration of the contractile powers of the living solids concerned in it, but must imply an alteration in the vital properties by which the constitution of the blood, in its relation to the surrounding textures, and its movement through

* Course de Phisiol. Gen. and Comp., vol. iii., p. 59.
† Vol. x.
‡ *Medical Times*, June 22, 1850.
§ *Vide* Foreign Prisons, p. 52.

them is determined."* Dr. Hughes Bennett has admirably demonstrated the *modus operandi* of the capillaries in exudations.† In a valuable work of Dr. W. Addison, the power colourless cells exert in controlling the nutritive changes is, I believe, correctly explained. While under abnormal action there is frequently an excess of cells, and they are diffused among parts adjacent;‡ I mean beyond their natural boundaries.

The present communication may be considered as an humble introduction to a more extended research into pathological hæmatolgy. I am happy to say Mr. Ancell is resuming the same subject in a series of able lectures in the course of publication;§ and it is impossible to overrate the importance of this branch of morbid anatomy. On reflection, we cease to wonder that diseases arise from modifications of the blood, when we take but a distant view of the numerous circumstances by which it may be altered. Atmospheric vicissitudes, aliment, drinks, respiration, and the condition of the nervous system, by which all the secretions are governed, exert a powerful influence on the blood, and produce numberless changes in the constitution. There would be a great advantage in having a more accurate mode of gauging the serum and crassamentum, since it would furnish some index of health and its deviations. The older authors were of opinion that the source of many disorders originated in the blood, but there is a great vagueness in their notions, for they were unacquainted with quantitative, physical, or chemical analysis. It has been reserved for modern physiologists to weigh and measure those realities which were before only matters of conjecture. Further inquiries are necessary to determine what value may be attached to the theory of disintegration of the blood. Of this I feel assured, we are advanced far enough to enable us to draw the conclusion that organic changes of the solids in general are not antecedent to an isolation of the elementary organisms, but depend on the dispersed and abnormal existence of the circulating corpuscular fluids. Hence the science of hæmatology deserves our highest consideration, and must be eventually estimated as the very foundation of all pathological investigation.

The examination of the blood is often desirable while the patient is under medical treatment; and in *post-mortem* inspections it should always be attentively noticed.

MM. Bequerel and Rodier have lately presented a memoir to the Academy of Medicine, "On Anæmia from Diminution of Albumen, and the Dropsy consequent thereon."

CASE OF OVARIOTOMY.

By GEORGE NORMAN, Esq., F.R.C.S.,

SENIOR-SURGEON TO THE BATH UNITED HOSPITAL.

Read at the Quarterly Meeting of the Bath and Bristol Branch, Dec. 19, 1850.

Elizabeth North, aged 23, enjoyed good health until March of the present year, when she began to have a disturbed state of stomach, pains extending over the abdomen, irregular menstruation, and in May she became sensible of a swelling on the right side of her body. She became the patient of Dr. Davies at the United Hospital, who has obliged me by furnishing the following particulars:—

"Elizabeth North was admitted into the United Hospital under my care on the 7th of June, and was discharged on the 2nd of July. At the time of her admission she was suffering much from derangement of her general health, and the menstrual function had been out of order for some months. At this time the tumour on the right side of the abdomen did not appear to be larger than an orange; no doubt was entertained of its being ovarian. The treatment was addressed entirely towards the improvement of her general health, and she quitted the hospital much improved in that respect, the tumour remaining the same."

She was admitted into the hospital again, under my care, on the 19th of September. The tumour then appeared to be nearly as large as the head of a child at birth; it was quite moveable in the abdomen and appeared to be attached below by the broad ligament of the uterus, for no doubt was entertained of its being a tumour of the right ovary. It was firm to the touch and gave no sense of fluctuation; her general health had much given way; she had pain extending over the abdomen, and at times severe cramps in the bowels; a fold of vagina protruded full two inches beyond the external pudendum, even when in the recumbent position, and she had endeavoured in vain to keep this up by a pessary before her admission. It was with great difficulty the os uteri could be felt; after a considerable examination it was found under the arch of the pubes. She was kept in bed, took iodide of potassium, and used iodine frictions to the abdomen, still the tumour increased in size and the pains in intensity.

The case was considered by my colleagues and myself, to be an ovarian tumour, and that if ovariotomy were ever advisable, this patient's case was one calling for it. The prolapsed state of the vagina, the weight of the tumour, and the continued pain, rendering it impossible for her to do anything for her support; the tumour was increasing and there seemed to be no hope of its growth being arrested. It was agreed that she should discontinue all remedies for a fortnight. At the end of that time her general health had not improved and the tumour appeared to be as large as the impregnated uterus at the fourth, or between that and the fifth month. I then explained to the patient the nature of the disease, told her that an operation had in some

instances been succesful in the same disease, but that the risk was great and the result doubtful. She replied that she had expected I should make the proposal to her, that she had quite made up her mind, and was ready to undergo the operation whenever I thought proper. A delay, however, occurred from her expecting to be unwell in two or three days, and it was not desirable to operate at or near that period. She became unwell, and after ten days the operation was fixed for the 8th of November. She left off meat for a few days before, and took a mild aperient. Fires were kept for two or three days in the operating theatre, and also in a small ward adjoining it, where it was intended she should remain after the operation, and where she was directed to go to bed the morning of the intended operation.

At twelve o'clock on Friday, the 8th of November, Dr. Davies, who kindly undertook to manage the administration of chloroform, put her fully under its influence in her bed, apart from all those assembled in the theatre adjoining. In a state of perfect unconsciousness she was brought into the theatre, and kept in that state during the whole time she remained there. An incision was made in the linea alba, about five inches in length, commencing an inch above the umbilicus, and avoiding that, it was extended downwards towards the pubes. The periosteum was raised with a pair of forceps, and opened to nearly the same extent; instead of any part of the tumour appearing, several convolutions of the small intestine protruded, these with some little delay were returned into the abdomen with great adroitness, by my collegue Mr. Gore, and retained there. During that time I had ascertained that the anterior parietes of the abdomen adhered very considerably, and firmly, to the tumour on each side of the incision; also that the adhesions below were considerable, and apparently insurmountable, and it was then discovered that a portion of the small intestine, full two inches in length, adhered firmly to the anterior part of the tumour. All hope, therefore, of removing the tumour being gone, no time was lost for the purpose of ascertaining its precise nature, but the integuments were brought together by five common sutures, straps of adhesive plaster were applied, some folded lint placed over with a bandage, and she was removed to her bed in the same state of unconsciousness as when she was brought from it. I saw her four hours after; she was then recovering from the effects of the chloroform, but was suffering from sickness, and pain in the abdomen. Pulse 115, of good strength and fulness. To take one grain of opium directly, and to have nothing but toast-water.

11 P.M.—Still in pain; has vomited the toast-water; pulse 116. To have one grain of opium every four hours.

Saturday, 9 A.M.—No sleep during the night; has vomited the toast-water three or four times; complains of great pain in the abdomen, not, however, increased by pressure, and no tension; pulse the same as last night. I had the satisfaction of hearing that she had no knowledge of having been removed from her bed. or any recollection of the operation. To continue the opium.

4 P.M.—Rather better; pulse 110.

11 P.M.—Has vomited, and is in pain; pulse 116. To continue the opium every four hours.

Sunday, November 10th, 9 A.M.—Has had a little sleep; had taken a little thin gruel, which was thrown up almost directly; has passed water; pulse 112. To take the opium every six hours. She remained much the same during the remainder of the day. There was some tension of the abdomen, and the bandage was taken off. There was very little pain on pressure.

Monday, 9 A.M. (the fourth day).—Had slept a little; still complains of pain; has vomited twice; has passed urine; tension of abdomen less; pulse 110. To continue the opium.

11 P.M.—She feels better; has vomited but once; pulse 110.

Tuesday, Wednesday, Thursday, and Friday.—During these four days she has been getting better, and has only vomited twice; pain less; has only taken the grain of opium about three times in twenty-four hours; pulse from 100 to 110. Has taken barley-water and gruel.

Saturday (the ninth day).—Still better; pulse 100; no vomiting; very little pain; no tension of the abdomen; the sutures removed; the wound partly united, and looking very healthy; bowels not relieved since the operation. To continue the opium, and to have a little weak beef-tea.

Sunday.—Has slept well; pulse 100. To have two ounces of castor oil, which, not operating, was repeated in the evening.

Monday, 11 A.M.—The oil has operated freely; pulse 90; the wound healed excepting at two points, the upper and lower end of the incision. From this time she went on well without pain or sickness. Pulse generally about 80.

On the fifteenth day after the operation it was ascertained that there was no protrusion of the vagina, and it appeared to me on examining the abdomen that the tumour was not of the same size as it was at the time of the operation. The lower part of the wound still remained open, but the quantity of discharge was too small to admit of supposing it came from the tumour. The diminution was supposed to arise from the total abstinence from food for some days, the low diet afterwards, and the constant recumbent position. After this time it appeared to me that the size of the tumour was gradually diminishing, although she was taking animal food, and by the end of November it was quite evident that the tumour was not more than half its former size. An examination per vaginam was made. The vagina was perfectly natural, and the os uteri was found in the ordinary position. The patient continued to improve, she gained flesh, and her countenance regained the healthy appearance. She was, however, kept to her bed, as the lower portion of the wound was not quite healed; soon after, however, it healed, and she was allowed to get up, from which she found no inconvenience, and she was shortly able to walk about the ward with freedom.

On the 9th of December Dr. Davies and I made an

external measurement of the tumour, and of its position, with the following results:—Distance from the right anterior spinous process of the ilium, to the edge of the tumour, one inch and a quarter; from the left spinous process, to the edge of the tumour, four inches and a half; distance from the umbilicus to the upper margin of the tumour, one inch and a half, (it is to be remembered, that at the operation it was necessary to commence the incision one inch above the umbilicus); transverse diameter of the tumour four inches, vertical diameter three inches and a half; length of cicatrix five inches. The feel of the tumour was harder and more irregular than before.

On the 17th of December Dr. Davies and I repeated the measurements, and found them to be the same, but she had gained so much in flesh and fulness of the abdomen, that it was not so easy to get the exact measurement. She expressed herself as being quite well, and she left the hospital the following day.

To account for the very considerable diminution in the size of the tumour which has taken place since the operation, is a matter of difficulty, and can only be one of conjecture. It may be that a certain degree of inflammation followed the exposure and the handling of the tumour, (though there was very little of the latter,) and that the vessels of the normal structure of the ovary may have poured out fibrin, and so formed a barrier between the cysts forming the bulk of the tumour and their supply, and this ultimately may have compressed and obliterated them; but be that as it may, the fact of a most important diminution remains, and as the young woman resides in Bath, I shall be enabled to know the more permanent result.

What has occurred in reference to this tumour may throw some light on cases were such tumours have spontaneously disappeared, of which I believe there are many instances. I had an opportunity of ascertaining one recently. A lady whom I had examined several times nearly twenty years ago had an ovarian tumour full as large as the one we have been considering. I saw her a fortnight ago on another occasion, and had the opportunity of examining the abdomen; I could find no trace of the tumour, her account was that the tumour had remained for some years as when I had examined it, that in the last few years it had gradually diminished, that latterly she could only occasionally find it, and that it was very small. I did not find it, but it may be, that being small, it remains for the most part in the cavity of the pelvis, and she described symptoms which made that probable, but it was not admissible to make an examination per vaginam, to investigate it. Another case has been recently told me by Dr. Robert Ferguson, of Park Street, Grosvenor Square, of a lady who consulted him for an ovarian tumour, of considerable size, and in whom, on her returning to him twelve months after, he could find no trace of it. I know another lady, whose abdomen I had frequently examined, who had a similar tumour full twenty years ago. Sir Astley Cooper also examined it, and gave the same opinion, I had given. In this lady, who is now living, it produced nothing more than inconvenience, and if I may judge from the altered appearance of her shape, the tumour must now be very much diminished, but I have had no opportunity of examining it. I have also known an instance where a considerable tumour of the kind formed a communication with the vagina, and after a continued discharge the tumour disappeared, and this person is now living. I know another lady who had for some years a tumour in the abdomen as large as a child's head, which also produced a displacement of the uterus and other distressing and painful symptoms, but which have now entirely ceased, and the tumour became diminished in size. Another instance has been related to me by Dr. Brabent, of a lady who had a large tumour in the abdomen for many years, which always become larger at the time of menstruation, and which gradually diminished after the cessation of that function, and finally disappeared.

I apprehend the case in which I have operated must be placed as opposed to the propriety of the operation, for if in that case it was not possible to foreknow the existence of insurmountable adhesions, I do not know how anything like certainty can be arrived at; and as this patient's life was certainly in jeopardy for three days, one cannot but think such explorative operations must be attended with considerable danger. Add to this the proportion of deaths after the tumours have been removed, and it will appear probable that the balance will turn on that side. The subject, however, is now fully and perfectly under the consideration of the profession, a great mass of information has been gained, and more will no doubt, for it is to be hoped that every case, whether successful or otherwise, will be recorded, and also those cases of ovarian tumours which have remained harmless, as well as those which have proved fatal, and then we may expect from our profession a dispassionate and correct conclusion.

ON THE COMPARATIVE SIZE OF THE HAND OF THE ACCOUCHEUR AND OF THE FEMALE PELVIS.

By GEORGE KING, Esq.,

SURGEON-ACCOUCHEUR TO THE DORCAS SOCIETY, BATH.

The following observations on the *size* of the hand and arm in the practice of midwifery and the size of the female pelvis and capacity of the outlet, may to some of your readers appear rather singular, and many others may feel and think as I do, that it is also singular, when we consider and observe the vast difference in the size and development of this important and useful member of the human frame, in those men we meet with who are daily engaged in practising in that delicate and peculiar branch of our profession. It is extraordinary that it has never attracted their attention, or been noticed by the various teachers and professors of the obstetric science or the general practitioners of midwifery; and it seems also to be unobserved by all authors on this subject, for we have published

lectures and instructions, as well as manuals, for the assistance and guidance of the young beginner in the practice of midwifery, but in none of them have I been able to discover the slightest notice or reference to the size of the hand and arm, they all give a most minute description of the various deformities of, as well as the diameter of, the outlet of the female pelvis, through which the hand is to be passed, and pages are written on the size and the choice of a catheter, or an œsophagus or rectum bougie, which is to be used for dilating those natural passages; but of the only instrument that can safely be used for the purpose of dilating the vagina, in order to get at the contents of the uterus, nothing is said. From the universal silence, we may be naturally led to think or suppose that all men's hands and arms are invariably of the same shape and size, and that, therefore, any allusion to it was useless and unnecessary in any catechisms or instructions that may be published or given to a tyro on his entering into this peculiar branch of the profession. Although midwifery is considered by the *pure* surgeon to be beneath his notice, and by others as a practice detached from physic and surgery, yet it partakes of both; and those who have made the medical profession their choice, and wish to rise in it, will find they must practice midwifery, and there is no part of our profession so likely to bring them before the public and into notice, as this. However degrading or derogatory it may appear to the pure surgeon to be thus engaged, the obstetric practitioner will find that in this department of his profession, not only his knowledge of the most intricate parts of anatomy and physiology will be required, but all his skill and energies, as well as moral courage, will be brought into action, in the performance of the most distressing and perhaps the most bold and difficult operations of surgery, and the most perplexing and frightful cases of the practice of medicine, and in those surgical operations the size of the hand will be of the greatest importance; yet it is unnoticed, and no one would for a moment imagine that there was any difference or variation in the structure and size of human beings, and that all men must naturally be of one uniform form and and size, and that there was, or is, no such thing among the human race as giants or dwarfs, and large, bony, muscular men, as well as small, thin, and slender skeleton-like men. These disproportions and differences in the form of the human frame are altogether passed over or forgotten by all writers and teachers of the obstetric practice. There are also persons practising medicine, and surgery, and midwifery, with monstrous large hands and arms, (as large as a sign-post,) while others have small delicate hands, with very thin and slender arms. There cannot be a doubt as to which of these ought to be selected for the practice of operative midwifery, and I consider that the former of these ought never to study, or if they did, not to make this branch of our profession their peculiar practice, being well assured that in very difficult or preternatural labours, when the introduction of the hand into the vagina is required, they are physically incapacitated to render that assistance under such circumstances, with that dexterity and ease that the case demanded, and the patient had a right to expect; and I fear they would add greatly to the sufferings, if not endanger the patient's life, while the latter would be able to render great assistance, and effect much good, as well as to be the means of mitigating a vast amount of suffering. This being my conviction, I am induced to draw the attention of the members of the Provincial Medical and Surgical Association, and the readers of the *Journal*, to the subject, and will endeavour to show them that it is of vital importance, in a practical point of view, that a man-midwife should have a small hand. And I have no hesitation in stating, that those gentlemen who have such monstrous upper extremities as I have described, ought never to think of practising as accoucheurs, as they will be sure to fail in their attempts to relieve their patients in some of the most distressing preternatural presentations, and while they are waiting for assistance or a smaller instrument, the chances are that they would lose their patient. In order to illustrate the subject, and to prove the very great difference in the size and the measurement of the hands of some, I need only to draw the attention of the reader to a daily and familiar occurrence, which may be seen at any glove shop. In trying on gloves, what pulling and tugging, what stretching, there will be, and frequently laceration, in the many forcible and ineffectual attempts that are made in endeavouring to get a large hand into a small glove. I understand from the glovers that they keep what they call large size men's and small men's; the largest measures *eleven inches*, and the smallest *eight inches* across the knuckles. What an awful disparity and difference in the size of an instrument, which is to be used indiscriminately, and without deviation or the least caution—as a dilator, and which is to be painfully forced through those structures lining and partly forming the outlet of the parturient passage in those frightful, sudden, and urgent cases, when there is no time for reflection, consideration, or substitution, for on its prompt and immediate application often depends the life of both mother and child. In all cases of protracted presentation, when it may be considered advisable or necessary to alter the position of the child in the uterus, the hand is the only instrument applicable or that can possibly be used for the purpose; yet we have no direction for the application of it, nor have the obstetric professors thought it of sufficient importance to inform their pupils whether a large one or a small one would be the best for use; nor is there any notice of the enormous difference in the size of them. Dr. David Davis, in his valuable work "On the Principles and Practice of Obstetric Medicine," says:—"It is well known, that the hand, when properly adapted to its object, is a much safer obstetrical instrument than any instrument that can be made." We all know that it is the indicator or eye of the practitioner in midwifery, and possesses a power far above all other instruments—that is, the property of touch; by this sensibility circumstances are made known, and the situation of the parts we are in contact with is conveyed to our minds,

and by this all our movements and operations are directed, and our medical treatment regulated. Sir Charles Bell, in his "Bridgewater Treatises," gives the following description of the human hand:—"The human hand is so beautifully formed, it has so fine a sensibility that sensibility governs its motions; so correctly every effort of the will is answered so instantly, as if the hand itself were the seat of that will. Its actions are so powerful, so free, and yet so delicate, that it seems to possess a quality—instinct—in itself; and there is no thought of its complexity as an instrument, or of the relations which make it subservient to the mind." This is a vivid and beautiful description of a perfect human hand, fully and properly adapted for all natural purposes as well as art. But all men's hands are not alike: they are not so beautiful, or so delicate, nor are they all so symmetrical as the one depicted by Sir Charles. They, therefore, are not all so well fitted for all the purposes for which they may be required to be used, and it is because I believe that an enormously large hand is a highly improper instrument to be used in many of the difficult and perplexing cases of midwifery, that I have been induced to make these remarks on the comparative size of it.

In all surgical operations we have the most minute directions given us as to the instruments to be made use of, as to shape and size, &c., and in all surgical works a description is given of them, and ample rules laid down for the selection of the most proper to be used, and their exact width, as well as length, is particularly mentioned, and we have also the exact dimensions of the pelvic aperture, and we have also ample directions as to what sized fœtal head will be likely to pass through it without assistance; but the outlet of the pelvis may be considerably diminished by distortion, and the inlet contracted, nevertheless, the hand must be got through in order to find out what is going on at the brim; and it may also be necessary to put the hand up into the uterus, but whether a large hand or a small one will be best fitted for the purpose of operations in this diminished space we are not told, and we often meet with a very contracted vagina, and this is to be overcome by sheer force; for there are no muscular fibres in this part to assist distension, the first application of the hand in the practice of midwifery is in the examination *per vaginam*, or as it is called by the old women, taking or trying a pain. This is done by introducing the fore finger slowly, and if we press with some degree of firmness on one side of the vagina, there will be less pain; if it is done more timidly it produces a tingling or irritation, which we should try to avoid. But this one finger exploring does not always reveal to us all that is going on, and often at this early stage of the labour, we may be obliged to pass up the whole hand, as the part presenting may still be above the brim of the pelvis. In such a case, the idea of an accoucheur with a tremendous hand and arm, to be in attendance on a delicate young girl, about 16 or 18, with contraction of the vagina, and with a flooding or preternatural presentation, is frightful, and the very thought of it to a person who has seen or had much experience in these difficult and monstrous cases, must make him shudder. The giving birth to a child being a natural process, it is not often that we have to interfere at all till the child is born; but being engaged and in attendance we ought, in every respect, to be fully qualified to act in all cases of malformation or complex labour. We all well know what a fuss there is made when a lady is likely to require the assistance of an accoucheur, as to who she shall have, and there are lots of consultations and inquiries among old aunts and cousins old dames and washerwomen, and they all take into consideration the age, appearance, character, dress, habits, mannerism, family, &c. &c., and all they know and believe, but very little is thought of their skill and ability. It has often surprised me that these expecting ladies should never think of the size of the hand. It is a proof that they can have but little idea of what the accoucheur may have to do with them, and it is also singular that the old advisers should not think of it, as they must have known a little of the application of it themselves. I believe in cases of contraction of the vagina, when labour has been impeded in consequence of a cicatrix or any other cause, it has been recommended, and it may be sometimes necessary as well as proper, to divide it by a knife, in order to allow the child's head to pass, but I have never heard it recommended to reduce or shave a little of a man's hand or arm off, in order that it might with more ease pass; but if any obstetric practitioner, with a very large hand, and a great monster arm, in cases of contracted vagina or deformity of the pelvis, was rash enough to attempt to turn a child in utero, or detach an adherent placenta, he would in my opinion be a very fit subject for such an operation. We do not always find uniformity in the parturient passages of females; there is a vast difference in the capacity of the vagina and dimensions of the pelvis as well as in the size of the hand and arm In some women we find the vagina large, loose, and flabby, and the outlet of the pelvis very large; such women will generally have very quick and easy labours, and we can be hardly ever in time to be present at the birth of the child. The place and the situation we occasionally find these patients in, would, if we did not know they were prudent and married women, lead us to suspect that they had some idea of concealment or evil attempt. I have always thought that those unfortunate females who commit infanticide, or had been guilty of concealing the birth of their child, must belong to this class of women, having a large and well-formed pelvis, and a lax and capacious vagina, and consequently must have very easy and quick labours. With the first child it is not easy for a woman to distinguish actual labour-pains, with the pressing or bearing down of the child, from an inclination to have a motion; and the attack may be sudden and rapid, without intermission, till the child drops from them without the possibility of their having the power of controlling or stopping its exit, or of being collected enough to give an alarm until it was all over, the child being born, and they having got rid, as they suppose so nicely, of what had for so many months caused them so much trouble and anxiety, and

so suddenly and unexpected, which was contrary to all their anticipations, that they could think of nothing but the pain and difficulties connected with labour. After recovering the shock and surprise produced by the birth of the child, which had annihilated from the mind all recollections of the past, and rendered them incapable of thinking of the future, they would only think of the present, and in a moment of the greatest excitement and fright, finding themselves alone and thus far undisturbed, and the child quite prostrated in a state of asphyxia from the fall or want of proper attention, they for the first time think of the unnatural crime of the destruction or concealment of the child, with minds in a state of the greatest agitation and excitement, and vacillating between shame, hope, and fear, and in this confused and frenzied condition, they are led to commit a most frightful and inhuman act, which had by them never been contemplated, and the very thought of such a deed half an hour before, in their calm moments, would have been the most revolting and horrifying to their feelings.

And I am disposed to believe that the size of the pelvis, and the capacity and structure of the parturient passages, are circumstances considering the intimate connexion, and action and reaction of the body and immaterial principles on each other, that have had much more to do with these tragical scenes than the organ of destructiveness or concealment. Women with a small pelvis, and a rigid contracted vagina, and perhaps a large child, must naturally be a long while in labour, which will allow time for the disquieted mind to compose itself, and an opportunity for reflection on their condition and the consequences connected with it; and I have no doubt that then the moral and finer feelings will overcome the brutal. These poor creatures, long before their trouble, must have been told that the passage of childbirth were awful and terrible to bear, and also have learnt, or had been given to understand, that the process of labour must be long, as well as painful and difficult; they, therefore, could not ever expect to give birth to a child without its being known, and charity would lead us to hope that no female would premeditate the death of her own offspring. I have long determined never to give such evidence, in any case of prosecution, as would be likely to convict a woman of infanticide, unless it was very clearly proved to me that it had been premeditated, and that *no* preparations had been made for it before the birth of the child!

I believe there is no rule of law that can prevent or restrain a professional man, when in the witness box on such momentous occasions, from taking into his consideration probabilities as well as facts, of which *he* is, professionally, best able to judge. But the indecision of medical witnesses is so generally known by juries, that verdicts are frequently returned in direct opposition to their testimony.

There is a case related in the *Lancet* some years back, of a medical man being requested by a magistrate to examine a young woman who had been suspected of giving birth to a child. She was examined by him six days after the child had been born. His evidence was, "That he found her vagina rather relaxed, so as to readily admit the whole hand," and this evidence was brought forward and intended to convict the woman instead of, as I think, acquitting her. The vagina, if not immediately, very shortly after delivery contracts to its natural state and calibre, and if six days after the giving birth to a child there was room to admit the whole hand, there must have been the usual capacity of the vagina, and no proof of recent delivery.

The following cases will tend to illustrate the latter part of this subject, and will show, as well as prove, how quickly and suddenly some women will give birth to a child. Those who have been engaged much in obstetric practice, must have been called to many sudden and rapid labours, and have, no doubt, witnessed some curious and frightful scenes, and have been, like myself, surprised and astonished with what rapidity the parts which are engaged in exppelling the child yield and dilate. As facts are generally valued above hypothesis, I will just name two or three out of the several cases of easy parturition that have occurred in my own practice, in order that they may be understood. I must also relate some of the circumstances connected with them.

Some years since a young man called on me to know at what hour in the evening a female friend of his could see me. I fixed the time, and at the appointed hour a very respectable-looking young woman, about 20, called on me. She was living in a family as lady's maid. She introduced herself by saying that she believed a friend of hers had called on me, and knowing the object of her visit, I put such questions to her as I then considered necessary, in order to ascertain the situation she was in. She did not seem to be very well versed in such matters, and I had some difficulty in getting out of her what I wished to know; from what I did elicit, I thought her to be about eight months gone in the family way, and this I told her, which appeared to surprise her much, and she became much affected, sobbed out she had hoped it was not so, and left my surgery very much depressed, without telling me where she lived or who her friend was. Early on the following morning her young man called on me to say that I was quite right, his friend was in the family way, and that she had had a child in the night, and he came to know what they were to do with it, as it was dead, without entering into any particulars as to what had happened in the night. I gave him directions as to how still-born children were usually buried. He was also to tell me that the young woman would call on me in the evening, which she did, and from her I got the following account of her labour, which, from her manner and natural simplicity, I believe was the truth:— After she left me the preceding evening she went to bed at her usual time, had no pain except of mind from what I had told her; her bedfellow was the housemaid, and she slept with her that night. She thinks she had slept about three hours, when she awoke up with great pain in the lower part of her bowels, with an urgent desire to make water; she got out to

the po and could not get off again till the child was born; she thought that she was on it about ten minutes. I asked her if the child cried; she replied no, but it had a good deal of hair on its head. Not being a coroner or a judge I did not consider that I had a right to ask any more questions. I gave her an anodyne mixture, and advised her to take very great care of herself. She ad that day waited on her mistress at dinner; she did very well, and got through it without being detected, in a house where there were several other female servants. Her milk was very troublesome for some weeks. She had been seen almost daily by her lady's medical man, and he has frequently prescribed for her without discovering what was the matter with her. The most astounding part of this affair is, that the birth of a child should have taken place by the side of the bed without rousing her fellow servant, no means having been used to prevent her knowing what was going on; mesmerism and chloroform were not so much in vogue then as they are in the present day. This woman is now married and I have attended her with six children since, and out of the six I was only in time to be at the birth of one, although I was always sent for directly she was taken in labour, the distance not being far, and the messenger generally found me at home. With the first after her marriage she was taken in the kitchen, and had but one pain and the child was born before she could be got up stairs.

The second case, a young girl about 18, called on me late on a Saturday evening, to tell me that she thought that she was taken unwell. I had not seen her before for several months. She had then consulted me on the subject of the suspension of the menses. While talking to me she complained of a sharp pain at the lower part of her stomach, with rather a queer look, which plainly portrayed what was going on; and although I am not a physiologist, I think I have practice enough in midwifery to understand the physiological signs of the face during labour-pains, so as not to be mistaken; I therefore gave her to understand that she was in labour, and soon packed her off home, as I clearly saw that there was a chance of my having an increase in my family, and a possibility of both doctor and patient being suspected of having contemplated the concealment of the birth of a child, not having made any preparation for such an event. About an hour after she left my house I was sent for in great haste. Her young man let me in, and then set off for a friend. I found her alone, sitting up in bed, hushing a baby, which she had laid across her abdomen; it was crying lustily, with the placenta still in the vagina, and the umbilical cord not divided. I separated the child, and removed the placenta. While I was dividing the umbilical cord, she said "I did'nt have much pain when the child came into the world." I remained with her till a neighbour came in. This young woman was living with her uncle; the poor old man could think of nothing but the cholera, and was below puffing away with the bellows to get some water hot. The old man's auditory nerve was not so sensitive as it had been fifty years before, therefore he did not hear the crying of the little brat. It was removed in the morning, and he knew nothing of what had taken place in the night. The girl did very well, and got married directly she was able to go out. The first child after the marriage also came into the world in a hurry. I was not in time. With the third, she had been out for a walk, and on her return went up stairs to the po, and the child popped into it; the po being half full of water, the child was suffocated. Although there were two or three females in the room with her, they were too terrified to lift her off and remove the child, but kept her in that situation till I came to her assistance.

The third case. One night last winter I was called, unexpectedly, to a married woman in an adjoining street, who had had two or three children. I found her sitting on the edge of the bed, very faint, and a child and the placenta attached, lying on the floor, and a large pool of blood across the room. The women who came in to her assistance were so aghast at the sight, that they became powerless, and could do nothing, as they said, till the doctor came. I did what was necessary. The account this woman gave me was, that she was aroused up from her first nap with a pain and an inclination to make water, and she was stooping down to get at the po, when the waters broke, and the child and the after-birth came away together, with one slight pain. Her husband was in bed; he immediately got up and ran for me, and left his wife by herself.

Such instances as these are numerous, and they most clearly show that women who have such quick and easy labours must have a large and well-formed pelvis, and the vagina and external parts must also be very relaxed, and easily dilated, which is a most satisfactory and convincing proof that during the act of parturition such women can have but little or no contracting or controlling power over the outlet, and this is, I believe, the cause of so many children suddenly passing through life into a fæcal repository.

There is a remarkable instance of easy delivery published a few years since by a French physician, that occurred at Arras, in France. A woman, 22 years of age, in the last month of her pregnancy, was suddenly affected in the night with acute pains in the abdomen, and considering it was what is called a bowel complaint, she immediately proceeded to the *garde-robe*. She had scarcely taken her seat, when the child was expelled *without any pain*, and she declared *she was totally ignorant of what had happened till she heard the child cry*. This is the only case that I have met with recorded of a woman having a child *without pain*. Children that come into the world so rapidly do not generally cry.

I have related these cases of sudden delivery with the humane view of showing, that at least some of the instances of children having been deposited in privies might have been accidental, and the parturition being nearly free from pain, the female might not have been aware of what had happened. I believe that many a poor girl has been overtaken with labour unexpectedly, and from not having been prepared for such an event, and the child dead, she is at once suspected of infanticide,

and dragged into a criminal court of law, and arraigned before a jury for an act of supposed crime, over which she had not the least command or power of controlling.

Although this is a subject that belongs to the obstetric department only, it may sometimes become a medico-legal question, and is I think, well worth the notice of professors of medical jurisprudence, for in some cases of infanticide and concealment of the birth of a child it may be very properly adduced as mitigating evidence.

Should you concur with me that this, as well as the size of the hand and arm, in the practice of midwifery, are subjects that have been neglected or overlooked by teachers and obstetric practitioners, you will perhaps allow their attention to be directed to it by the insertion of my remarks in an early number of the *Journal*.

Bath, September 24, 1850.

CASES OF FEVER, WITH REMARKS.

By MICHAEL FOSTER, Esq., Huntingdon.

It may not be uninteresting to give a brief report of the outbreak of a fever of a fatal character at the Huntingdon Union Workhouse, in January, 1847; more particularly as a fever of the same type, with various modifications, has just now prevailed at Heringford Abbotts, a village four miles north-east of Huntingdon. I will give the first case in detail, then a copy of the minutes, as reported to the Board, then a summary, with remarks.

Mary Archer was admitted into the lying-in ward about a fortnight ago, in the family-way by a man named Joseph Martin, of Great Catworth. During this period she was observed to suffer from a depression of spirits, but never complained of being in any way ill. Had been very sick on the Sunday week previous to her confinement, and afterwards occasionally, and on each occasion had brought up a darkish green-coloured fluid.

On Tuesday, the 5th of January, 1847, at one o'clock in the afternoon, the attention of the medical attendant was first drawn to her. He found her very feverish; tongue brown in the centre, with reddened tip and edges; pulse small and weak, not unusually quick; the bowels had been relieved the evening before; had been sick frequently during the day, vomiting dark coloured fluid. At six P.M. was sent for to attend her in labour. Found the head pressing on the perineum, which was very turgid, especially just anterior to the anus, where its colour was almost black; the bag of the membranes protruded, which were also of very dark colour; the head was lying a little across, the left ear being easily felt at the back of the pubes. Learnt that she had been just in this way two hours. At nine P.M. she was delivered of a dead male child, about the full period, (according to her reckoning wanting a week.) The placenta came away immediately. Uterus contracted; no hœmorrhage; had had no strong pains at any time during the labour; she was sick every now and then afterwards; seemed restless; had constant alternating cold and hot perspirations; and complained of fainting sensations; drew her breath short, and moaned slightly occasionally. Took a cup of tea and toast about ten o'clock; in half an hour afterwards was free from sickness, and appeared more comfortable, and remained so for three quarters of an hour. From this time (eleven o'clock) she was tolerably comfortable, taking a little brandy and water occasionally to allay the sickness, which continued at intervals. Later at night she became restless, breathing short and quick; the neck, face, and lips became very blue; and having rested quietly three quarters of an hour, she raised herself and suddenly expired, at two o'clock in the morning.

Post-mortem, twelve hours after death.—Abdomen contained a large quantity of bloody serum; uterus natural; liver healthy, larger than is usual; stomach much disturbed with flatus; contained a dark coloured fluid, showing patches of inflammation here and there. There was serous fluid effused into the pericardium. Heart healthy and of natural appearance; the right ventricle and auricle were full of very dark coagulated blood; the left were also full of blood, but fluid. Lungs were healthy. The œsophagus and the cardiac orifice of the stomach were dark coloured. There was much venous congestion of the body generally, but especially in the neck. The contents of the stomach were analyzed. Rheinsch's process for arsenic, protochloride of tin, for corrosive sublimate, and other tests, were tried, but no signs of any poison were discovered.

Minutes reported to the Board of Guardians.

"Monday, January 11, 1847.

"I beg to call the attention of the Board to the sudden appearance of fever in this house of a very severe and dangerous character, partaking of the type of bilious remittent at the onset, rapidly leading on to typhoid disorganization of the tissues. The first case was that of Mary Archer, aged 25, who was taken ill, with severe vomiting of dark brownish-green coloured fluid, extreme prostration, premature delivery, and died in the course of twenty-four hours. The *post-mortem* examination showed extensive effusion of turbid fluid into the peritoneal cavity, great enlargement of the liver, and much distension of the stomach (flatus;) its internal surface very red in some parts, and of a dark slate colour in others. The right side of the heart was loaded with blood, quite black, as also were the vessels of the neck and throat. The next case, that of George Bell, aged 12, exhibited the same severe vomiting violent pains of the head and belly, and who died in three days. Since then, and up to this day, nine more cases of greater or less degree of severity have taken place. I have recommended these to be separated as much as possible from the other inmates; chloride of lime to be put into most of the rooms, and large quantities of unslacked lime in all parts of the drains; also the pregnant women to be removed from the house.

"15th.—Six more cases have appeared since Monday.

Three have died, viz., Savage, Howe, and Baram; the last was a weak epileptic patient, quite unable to withstand further illness. Three or four of the other cases are of mild character, and going on favourably; Bond, Rowell, and Selby are still very ill, and upon the whole the fever spreads, but the more recent cases are less severe in their character. No men have been attacked. I reported to Sir John Walsham, according to his request, 'that although there was some room to suspect the fever might have been brought to the house by a Dutch sailor boy (a tramp), yet the evidence was not satisfactory; but when the drainage throughout the whole of the workhouse, and the open and overflowing state of the cess-pools are examined, I have no hesitation in saying there is quite sufficient to generate fever of the worst kind.'

"January 22nd.—Since last week there have been only two new cases of fever. Elizabeth Wright and Martha Bell, both nurses. They are going on well. There have been three deaths—viz., Ann Saunders, an old debilitated female, Ann Whitehead, a blind person, very weakly, who had suffered long from scrofula, and Lydia Jackson. All the other cases are doing well and promise recovery.—"29th. No new case of fever.

"February.—The state of the workhouse as regards fever is much better. No new cases.

"March 5th.—I think pregnant women may now be admitted."

SCHEDULE A.

Name and age of Patient.	Nature of Disease.	Duration of Disease.	Treatment and Diet.
Mary Archer, aged 26 ...	Childbirth. Bilious fever, severe vomiting, extreme prostration, short rapid respiration, venous congestion, abdomen distended with flatus, effusion into peritoneum, gastritis	Died in 18 hours after seizure	Salines
George Bell, aged 12 ...	Symptoms the same as last, gastritis two days, meningitis one day	Died in 4 days	Ant. Tart. et Mag. Sulph., &c. Hyd. c. Cretâ, Pulv. Doveri; cold lotions
Rebecca Baram, aged 50	All her life subject to epilepsy. Symptoms as the last	Died in 4 days	
Sarah Savage, aged 23	Remittent. Premature delivery after 6 days, peritonitis 3 days, delirious 2 days before death	Died in 9 days	Leeches, blisters, calomel, and wine
Eliza Howe, aged 17 ...	Confinement, followed two days after by fever. Peritonitis	Died in 3 days	Treatment as the last
Ann Whitehead, aged 23	Blind. Scrofulous ulcers, fever, and erysipelas. Delirious	Died in 8 days	Wine during two days
Ann Saunders	Debility and old age. Fever	Died in 4 days	Wine, &c.
Lydia Jackson, aged 35	Remittent. Gastritis, meningitis two days, severe	Died in 7 days	Leeches, blisters, wine, calomel, ointment, lotions
Mary Bond, aged 23 ...	Remittent fever followed by miscarriage after 1 month. Recurrence of fever, mammary abscess, extreme debility, vomiting, &c.	Ill altogether 6 wks. Died three weeks after abortion	
George Gillson ... } Frederick Eates ... }	Attacked mildly	Recovered in 3 or 4 days	Milk, wine, and medicine
Sarah Leach, middle-aged	Bad constitution, fever and severe diarrhœa	Cured in 14 days	Hyd. c. Cretâ, Pulv. Doveri, &c., as the others
Hannah Selby, aged 20	Had gonorrhœa. Attacked severely, peritonitis, delirious	Recovered in 20 days	Leeches, blisters, wine, ammonia, Hydrarg. cum Cretâ, and Dover's powder, &c.
Sarah Hall	Fever ran its course, not severe	Recovered in 14 days	
Ann Johnson	As the last.	Recovered in 14 days	
Emma Heddens	... ...	Recovered in about 14 days	
Elizabeth Wright, (Nurse)	... ...	Recovered in about 9 days	
Sarah Rowel, aged 14	Attacked severely. Peritonitis	Convalescent in 14 days	Leeches, blisters, &c.
Martha Bell (Nurse) ...	Attacked severely. Erysipelas	Convalescent in 10 days	Wine, &c.
Maria Hall (Hired nurse)	Attacked very severely. Peritonitis, erysipelas, inflammation of the glands of the neck.	Ill from 18 to 20 day	Leeches, blisters, calomel, sinapisms, Hydrarg, c. Cretâ and Dover's powder, ammonia and opium.

SCHEDULE B.—*Summary of Deaths and Recoveries.*

Date.	Name and Duration of Disease.	Nature of Disease.
Jan.	6th.—M. Archer died in 18 hrs.	Confinement
	9th.—Geo. Bell ... 4 days ...	
	,, 14th.—Eliza Howe ... 3 days ...	Confinement
	,, 15th.—R. Baram ... 4 days ...	Old epileptic
	15th.—S. Savage ... 9 days ...	Premature delivery
	,, 17th.—A. Whitehead ... 8 days ...	Blind. Very scrofulous
	,, 19th.—A. Saunders ... 4 days ...	Weak and old
	,, 20th.—L. Jackson ... 7 days ...	
Feb.	9th.—Mary Bond ... 1 mth. ...	Abortion fifth month

Of the eleven who recovered, two were boys who were only mildly attacked and soon recovered.

Name.	Duration of Disease.
Elizabeth Wright	Recovered in 9 days
Martha Bell	,, in 10 days
Sarah Rowell ...	,, in 14 days
Sarah Leach ...	,, in 14 days
Sarah Hall	,, in 14 days
Ann Johnson ...	,, in 14 days
Emma Eddens ...	,, in 14 days
Hannah Selby ...	,, in 20 days
Maria Hall	,, 18 to 20 days

The remaining nine females had the fever more or less severely.

REMARKS.—*The type* may be considered bilious-remittent, great derangement of the biliary system, rapid and destructive action of the serous membranes of the brain and abdomen; the latter, particulary in pregnant women, who seemed especially susceptible, and in some cases erysipelas appeared.

Cause.—No doubt gaseous exhalations from the overflowing drains and open cess-pools in several parts of the premises. So closely did the first case resemble poisoning, that I analyzed the contents of the stomach with the view of ascertaining whether any poison had been administered, and it was whilst musing upon what could be the cause of death that a second case (G. Bell) appeared with analogous symptoms. The same causes in operation at Huntingdon. When the drains were cleansed the fever subsided DIRECTLY. Whether infectious or not, three of the nurses, previously in good health, were attacked, and the fever was confined entirely to the *female* side of the house.

Four pregnant women were seized; all died.* Of the twenty cases (out of seventy-three females in the house) nine died.

Such was the fatality that much cannot be said for treatment. In the earliest stage the tartrate of antimony, in full doses, was the most beneficial; if not much allayed by this nothing very useful. The most satisfactory steps were the removal of all the inmates that could be moved, and the *non admission* of *any others.*

Huntingdon, Sept. 19, 1850

* One pregnant woman was removed and she escaped; the two others were attacked before measures could be taken to remove them, and it was not known that the third was pregnant.

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

REPORTS OF CASES ADMITTED UNDER DR. DAVID NELSON.

Extracted from the Clinical Records,

BY W. J. MOORE, ESQ. M.R.C.S., AND L.A.C., RESIDENT MEDICAL OFFICER.

CASE XV.

Case of Thomas Sheridan, aged 20. *Temp. nervous. Affected with Phthisis, terminating in death. Admitted March* 4.

HISTORY.—This patient stated that he was only conscious of being ill three months before. At Christmas he caught cold, and had since that time been troubled with cough, which had at first been moist, but had become drier under medical treatment. He had of late become pale and lost flesh.

Symptoms.—On examination, the tongue was found red at the point and edges; bowels were costive, and the discharge dark, and the urine was scanty and high coloured; the expectoration was sometimes thick and yellow, and at other times thin and tenacious; he had not sweated since he began to wear flannels; the chief dulness was observable over the right side, anteriorly; pulse 140, respiration, 36.

Diagnosis.—That there was tubercular deposit, chiefly in the right lung, and afterwards excavation and cerebral effusion.

Treatment.—He was a quiet but spirited young man, and was ready to submit to any treatment. The plan decided on was to employ derivatives, expectorants, tonics, and alteratives; and the orders were:—Hab. Hydrarg. Chlorid., gr. v., statim et Ferri. Carb., gr. iij.; Pulv. Aloes, Pulv. Ipecac. utrq., gr. j., omni nocte. Ol. Aselli, dr. j., ter die; Tinct. Opii Camph., dr. j., ter die; Acid. Sulph. Aromat. gtt. xxx.; Sulph. Quinæ, gr. j., omni nocte. Ap. ves. lat. dext.

7th.—The cough was much easier, and the expectoration profuse; he had had no sweating, but his tongue was coated, and he felt his throat so enlarged as to impede his breathing and excite cough from time to time; he was also hoarse. On examination of the chest, again the dulness was observed to be most apparent under the centre of the right clavicle, where there

was also pectoriloquy; while a peculiar reverberation, noticed by Dr. Nelson in many other patients, was also elicited under the stroke of the hammer against the pleximeter. Pulse 120, respiration 40. He continued the medicines, and had two leeches applied to the throat.

12th.—Cough had been rather easier, though he was now afraid he had caught a fresh cold; the throat felt better; the expectoration was muco-purulent, with a quantity of loose granular matter; pulse 140. Continue medicine.

18th.—Cough was easy and appetite good; but he complained much of the action of the heart. Pulse 160, respiration 48. As bleeding was inadmissible, digitalis was now added to the pectoral mixture.

19th.—He continued free from perspiration, and the appetite was still good, and he bore the oil well, but the expectoration was still profuse and muco-purulent; the action of the heart was violent, and pupils much dilated; pulse 120. Continue medicine.

22nd.—His perspirations had returned; expectoration was less, but the cough much the same; the appetite had diminished, and he was confined to bed by severe headache, always increased on rising; the pupils were still much dilated; pulse 148, respiration 38. He was advised to keep his head low, and continue his medicines. He died that same night, about twelve o'clock, having just before got out of bed and visited the water-closet. He died without the slightest noise which could have excited the notice of any one present.

Post-mortem.—The right lung had four large caverns and numerous smaller excavations; the largest was in the site where the pectoriloquy was heard. The left lung was also infiltrated, but not to the same extent. There was some degree of inflammation in different parts of the lungs, surrounding and apparently produced by the tubercular deposits. The abdominal viscera were healthy, but there was a great quantity of fluid in the ventricles of the brain.

Observations.—It may be fairly concluded that this case was of much longer standing than what the patient stated. Except in acute tuberculosis, it was very improbable that so much havoc could be effected in three months. It is much more probable that the difficulty of breathing, slight cough, &c., had come on so gradually that the young man paid little attention to them, which illustrates again what may be the condition of many people who pass one cheerfully in the street. Until softening commences there may be very few alarming symptoms; as we also find that those peculiar symptoms depart as soon as we may have arrested the progress of softening, although the dulness on percussion may remain the same as ever. The respirations and the pulse were here high from first to last, the lowest degree of the former having been 36, while they had risen as high as 48; and the lowest degree of the latter having been 120, while they had mounted as high as 160. The medicines were borne very well, and there was no lack of hopeful spirit on the part of the patient. The immediate cause of death was obviously effusion into the ventricle, arising from the anæmic condition, as he was like a wand, full six feet high, pale, and bloodless. The effusion was indicated during life by the highly-dilated pupils; but local blistering in such a case would not have reached the original cause.

Provincial Medical & Surgical Journal.

WEDNESDAY, JANUARY 8, 1851.

It has not been the custom for the Editors of this journal to comply with the usual practice, at the commencement of the year, of putting forth a review of their past proceedings, or a prospectus of their plans for the future; but circumstances have occurred within the last few months which render this proceeding desirable at the present juncture.

It cannot be unknown to the members of the Provincial Medical and Surgical Association, that in our Editorial capacity we have given offence to a section of our Society, in consequence of certain views which we have taken of medical politics, and though it is not denied that those views were in accordance with the sentiments of the great majority of the Association, it is maintained by some members of our body, for whose opinions we have the highest respect, that however we may have aided the cause we espoused, we have done injury to the Association by sowing the seeds of discord among its members. This opinion is backed by the assertion, that the Provincial Medical and Surgical Association was established for several specific purposes, one of which is the promotion of harmony among its members, and that, consequently, it is better to avoid altogether such topics as may in any way militate against the interests, or interfere with the prejudices, of the individuals composing our readers.

We have in this manner been compelled to consider the propriety of avoiding all discussion of medical politics, since it is impossible to enter upon the subject in such a way as to avoid bringing in any matter bearing upon the interests of some parties; and if we are to express any opinion at all, we can scarcely avoid the risk of giving offence. Our own impression upon the question is, that in rejecting medical politics from the editorial articles of this journal, we should most assuredly impair the efficiency, and diminish the interest, of its pages, for there are

many readers of our columns who see no other medical periodical, and who at the same time wish to be kept alive to the proceedings of their *confréres* who may be so situated as to have the reins of power in their hands; but, at the same time, we think it due to those who have expressed their opinions to us as adverse to our own, to take a middle course, at all events until the next annual meeting, to be held at Brighton, and thus to avoid, as much as possible, the discussion of any irritating or political subjects.

In making these few observations upon our future proceedings, we have studiously avoided any reference to the past, because we should not wish to incur any risk of raking up differences, which we trust are now gradually subsiding. We would simply repeat what we have previously declared, that we have, in all we have inserted, studied as much as possible to avoid personalities, and have only written what we considered ourselves bound to put forth, viz., our honest convictions upon the point to be discussed.

In coming to this determination we have been somewhat influenced by the fact, that in the forthcoming crisis, there is a much better chance of free and fair discussion among our contemporaries than was the case at the corresponding period of last year. At that time we were alone in our opinions upon the subject of the Reform of the College of Surgeons, as the grand desideratum in medical politics, whilst at the present time this view is supported by the Editors of the *Lancet* and *Medical Times*, and is only opposed by the Editor of the periodical recently established for the specific purpose of defending the propriety of establishing a new or third incorporation. The subject will thus have a chance of being fairly investigated, and for the present, at least, we leave it to the tender mercies of the gentlemen conducting these several periodicals. In conclusion, we have only to lament that from the peculiar circumstances in which we are placed, we should have a responsibility, divided between our numerous associates, (who claim to be also our directors,) and the profession at large. We think most decidedly that the latter should have the preponderance; but if our opinion should not meet with the general accordance of our fellow-members, then we would suggest the propriety of altering altogether the form of the *Journal*, and of converting it into a periodical *sui generis*, since its leading articles will otherwise appear to many in the same light as that frequently-propounded illustration of inanity—the tragedy of Hamlet, with the part of Hamlet omitted.

At the request of Dr. Robertson we beg to draw attention to the distressing case alluded to in the advertisement on our wrapper; it is that of a gentleman, aged 44, residing at Bedford, properly qualified, highly educated, and of irreproachable character, who is disabled by paralysis, and, with a wife and eight children, is in great distress.

A few of his friends have determined to appeal to the sympathy of his professional brethren, in the hope of being able to raise such a sum as shall place him above the want of the necessaries of life, and we sincerely hope that the appeal will be responded to by all who can spare the small sum which may be required for such a benevolent purpose.

Reviews.

Hydrocephalus Reconsidered; and its Relations to Inflammation and Irritation of the Brain defined, with Cases from Hospital and Private Practice, &c. By Thomas Weedon Cooke, M.R.C.S. London: Highley, 1850.

In this little work we have laid before us in a brief manner, the record of the author's experience in children's diseases. His chief object in the present publication is to call attention to the importance of distinguishing between *inflammation* and irritation of the brain, but he also endeavours to show that when the pathology of the disease, improperly called hydrocephalus, is correctly understood, its treatment is not so hopeless as is commonly represented.

The three first chapters may be considered as introductory, and consist of general observations on the physical peculiarities of the brain in infancy, and on the anatomical characters of inflammation and irritation. In the fourth chapter the author points out the error of calling the disease "hydrocephalus," a term which only expresses one, and that not an absolutely constant, symptom. He next devotes two short chapters to the description of acute cerebritis, which, contrary to the received opinion, he maintains to be a frequent disease, and of cerebral irritation, under which title he includes those conditions which have received the names of subacute

hydrocephalus, tubercular meningitis, erethism, &c. His treatment of the former is actively antiphlogistic, giving mercurials in the first stage, with iodine in the stage of collapse. In the latter class his treatment is sustaining, with iodine and chlorate of potash, and on this plan it appears that his success far exceeds that generally experienced. The author has done well in criticising the common habit of confounding all the cerebral diseases of infancy under one term—hydrocephalus, which induces too many to adopt an injuriously depletory line of practice; but it appears to us that he has not been sufficiently precise in defining the several pathological states of the brain, which are manifested by symptoms properly denominated those of irritation. In fact, under this latter form of cerebral irritation should be classed two distinct cerebral conditions—one, that of simple nervous exhaustion, which may be likened to delirium tremens in the adult, and readily curable, the other an asthenic condition, associated with tubercular deposit in the membranes, and softening of the cerebral centres, which is known as strumous meningitis, and which, with deference to Mr. Cooke, we maintain to be the most fatal of infantile diseases. We can only explain the author's alleged success on the supposition that, as would frequently be the case in London, he has met with the former class of cases, arising from dentition, diarrhœa, &c., and has confounded them with the other. In stating this to be our opinion, we do not, however, intend to speak slightingly of Mr. Cooke's diagnostic powers, for we believe that the symptoms of the two condtions alluded to, are often so similar as to preclude a positive diagnosis during life, excepting as it may be afforded by the results of treatment.

Mr. Cooke has entered upon a very interesting subject of research, and we trust that one day we shall find him treating it greatly more in detail.

On the Management of Infancy, with Remarks on the Influence of Diet and Regimen. By CHARLES HOGG, M.R.C.S., L.A.C., &c. London: John Churchill.

WE regret that it is not in our power to speak in favour of Mr. Hogg's volume. As a guide to parents it was needless, while Coombe's writings are extant; and as regards professional readers we do not for a moment suppose that the author himself could imagine that it contains any available information. That he never contemplated other than nursery admirers is, however, probable, or he would not have been at the pains to inform us that *hepatic* meant "*liver*" disorders, and that struma was also known as "king's evil." Infantile pathology offers an extensive field for original observation, and we think Mr. Hogg might in this be employed more creditably to himself, as well as more profitably to others, than he has been in producing the present compilation.

Proceedings of Societies.

READING PATHOLOGICAL SOCIETY.

THE RETROSPECTIVE ADDRESS,

DELIVERED AT THE NINTH ANNIVERSARY OF THE READING PATHOLOGICAL SOCIETY, JULY 24TH, 1850.

By CHARLES H. GAMBLE, Esq.,

DISEASES OF THE REPRODUCTIVE SYSTEM.

Continuing the same subject, and after adverting to the preceding cases, Mr. WALFORD, on the 30th of January, 1850, related the following case :—

Puerperal Peritonitis.—Mrs. B., aged 35, was confined on January 2nd, of her sixth child. Her previous history was not very favourable, as she had had two miscarriages, and for a long time had been subject to leucorrhœa, with pain at the bottom of the back, puffy eyelids and hands, and a general anæmic condition, urine normal. Her labour was very easy, and she continued to do well to the 5th, (the fourth day from delivery,) when she complained of slight pain at the bottom of the abdomen over the right side of the uterus, with tenderness on pressure. There was not a sign of constitutional disturbance. A laxative had been taken, so a linseed poultice was simply ordered.

On the 6th, at 10 A.M., her local symptoms were in every respect the same, but in the night she had experienced a slight chilliness, and her pulse was quickened. Four leeches were ordered, and a small dose of grey powder and Dover's powder every four hours.

At 4 P.M. the abdominal pain and tenderness were both extended and increased greatly; her legs were drawn up, and a deep inspiration was painful. Pulse 120, small, not wiry, but intermitting. Her countenance was anxious, and the lochia and milk secretion diminished. Mr. Walford, remembering the former cases, now "determined on bleeding until the pain and tenderness were lessened, the pulse lowered, and a

---

* Continued from page 713 of last volume.

nearness to syncope indicated." A quart of blood was taken away, eight grains of calomel immediately administered, and eight leeches applied to the abdomen. In the evening she was rather easier. An aperient and injection, if necessary, were ordered, and two doses of three grains of calomel, and a grain and a half of opium, once in four hours.

On the 7th, at 10 A.M., Dr. Woodhouse saw her in consultation. She was then better, but the bowels having but imperfectly acted, an injection was ordered. The bladder was emptied, the vagina washed out with a weak chloride lotion, and two grains of calomel, and half a grain of opium, every four hours prescribed. In the evening she was improving. Lotion and catheter again used.

On the 8th still improving, and gums slightly tender. The mercury was continued in diminished doses, and a blister to the abdomen ordered. With the exception of some mental excitement, which came on late this same evening, and which was quieted by half a grain of morphia, she from this time gradually improved.

Mr. Walford then said he was aware the nature of the case might be fairly disputed, but to those who attended her there seemed no doubt of its being puerperal peritonitis, and if that were not puerperal fever, he did not know what puerperal fever was. Seeing the success of active treatment in this case, he regretted its non adoption in the former ones, and he felt inclined to recommend its more general adoption in cases of a similar nature. He thought also the constitutional symptoms should not be allowed to interfere with the physical evidence of local inflammation, at least during the first few hours from attack. Dr. Wells differed from Mr. Walford in some points—passing from peritonitis to puerperal fever was passing from a part to a whole. There might be cases of peritonitis and of phlebitis, but in these latter he could not agree in the general application of blood-letting, which would only promote a more rapid absorption of purulent matters and render the debility greater.

Mr. PAYNE had had large experience in these cases; and the one just related by Mr. Walford he considered pure peritonitis, and distinct from puerperal fever. There were great varieties in the symptoms of peritonitis, which, perhaps, more than from any other cause, arose from the difference of constitution of individuals. There might be peritonitis without pain. He did not approve of bleeding in all cases, yet he found it and mercury very successful in the early stages; but he would caution practitioners against the use of purgatives by which he had often seen the disease produced. He had not seen much of puerperal fever in his own practice, but he saw it when it prevailed in Oxford, and he thought it quite a different disease from that described by Mr. Walford; but he believed the condition of the atmosphere had much to do in determining the nature of the malady.

Puerperal Fever, (Phlebitis).—On the same evening Mr. YOUNG related a case of fever, which had lately occurred to him. The labour had been complicated by hour-glass contraction of the womb and slight adhesion of the placenta. She seemed doing well at first, but about eighteen hours after delivery she became delirious, and complained of great abdominal tenderness. On the following morning, or about thirty hours from delivery, she was found with an anxious countenance, a quick and rather full pulse, the tongue coated with a white fur, great thirst, abdomen tense and tender, lochia scanty and fœtid; bowels relaxed. Ordered—vaginal injections, ten leeches to the abdomen, and the grey and Dover's powder every four hours. The next day Dr. Wells saw her in consultation, when she appeared very drowsy, breathing heavy and sighing; the pulse 160 and very feeble; tongue dry, coated with a brown fur; abdomen very tympanitic; and lochia dark-coloured, purulent, and most offensive. She was ordered camphor and grey powder, with turpentine fomentations, and a blister to the nape; also brandy frequently. She died on the fourth day after confinement.

Mr. HARRINSON then said that he agreed with Mr. Payne that puerperal fever was of much less frequent occurrence than was commonly supposed; for out of six or seven hundred cases of labour he had only met with two genuine cases of the disease, both of which he was the innocent cause of inducing, from having been attending a case of phlegmonous abscess before being called to the labour. He believed that many cases of the so-called disease were mere intestinal irritation, in which the pain was more intense than in pure puerperal peritonitis, and where the secretions were all unhealthy, and required three or four days for their correction.

On the 27th February Dr. WELLS read a paper on *puerperal fever*, with the object of disproving the idea that all cases of puerperal fever would be benefitted by bleeding. He followed Dr. Fergusson in dividing these cases into four classes, viz., the *peritoneal*, the *gastro-enteric*, the *nervous*, and the *complicated*. He considered them, however, all to arise from one source—vitiated blood; and that, in every epidemic, one form was liable to run into another, and to assume its characteristic features.

Dr. Wells then proceeded to give the following cases, as instances of these forms of the disease, commencing with the complicated, characterised by deposit into the pleural cavity:—

Mrs. H. was confined on the 1st of August. For six days she did very well, when she was attacked with pain and tenderness in the left iliac region, which subsided under the use of leeches and sedatives, but in two days returned, with severe cephalalgia, quick pulse, and furred tongue; and the abdomen generally became tender and tympanitic. On the twelfth day from her confinement the respiration became accelerated and painful, and dulness was discovered at the base of the left lung. The lochia, which up to this time had been free from fœtor, now disappeared, and the breasts became flaccid. The bowels were relaxed, probably from the use of calomel; the tongue furred and brownish; the pulse 120—130; the urine high-coloured; and the countenance anxious. The intelligence was throughout

perfectly clear, which the author remarked was a peculiar feature in this class of cases. After this the abdominal tenderness somewhat decreased; but the pleuritic symptoms greatly increasing, she became gradually exhausted, and died on the sixteenth day from confinement.

The next two cases were considered instances of the *nervous form*. In the first, after doing well for some days after labour, the patient began to be irritable, perverse, and desponding, and on the seventh day her speech became affected, and she was unable to articulate. The abdomen became tympanitic, but not painful; the bowels were confined; the pulse quick and feeble; the tongue clean and moist; the lochia slightly fœtid. The next day she was worse, the breathing being hurried and somewhat stertorous; and she refused all food and medicine. Low typhoid delirium set in, and she died comatose on the tenth day from her confinement.

In the second case the patient was taken ill on the eleventh day, with shivering, restlessness, and feverishness. The symptoms afterwards were great wakefulness; delirious rambling, but answering rationally; tympanitic abdomen; costive bowels; and a weak tremulous pulse; the tongue being pale and moist; no vomiting; and no complaint of pain. She gradually sank into a comatose state, and died at the end of a month from her confinement.

As an instance of the peritoneal form the author mentioned the case of —— whom he had attended with Mr. Young, and which has been already detailed. The author then said that he had brought forward these cases as instances, that under the generic term of puerperal fever different species of that disease were comprehended, and that no one line of treatment could be applied to the various forms of that affection. He had no doubt that in the peritoneal form, bleeding was an important item in the early stage; but in the others he thought it very questionable whether much bleeding would not tend to promote the absorption of a larger proportion of those noxious animal matters, whose existence in the uterine cavity is most probably the source of the majority of puerperel fevers.

Moreover, in order to bleed it was necessary to have a pulse which warranted such a measure, and this he believed was seldom the case in this disease; it certainly had never existed in the four cases related.

Experience had also shewn that in the nervous or atonic form, large bleeding, and indeed depletion to almost any extent, was very liable to be followed by immediate sinking, while a sedative treatment would frequently subdue the disease.

In the gastro-enteric variety which appears to depend partly on irritating matters in the large intestines, much more relief will follow the removal of those matters by mild aperients guarded by sedatives, than will result from the free use of the lancet, which by needlessly lowering the strength would convert a generally manageable form of the disease into one of uncontrollable and complicated malignity.

Mr. Payne then said that from his experience in Dublin and Oxford, he believed there was a disease in which inflammation was merely accidental, and where bleeding could not be attempted. Local depletion might sometimes be useful, but it ought to be used early.

Mr. Jeston, sen., after the experience of thirty-five years' practice, could corroborate Mr. Payne's opinion in regard to bleeding. He then read a case of *puerperal fever*, arising in a woman who had been in attendance on her father, labouring under erysipelas of the legs, which attacked herself in the foot, travelled up to the thigh, premature labour came on, and she died in a week from the commencement of the erysipelas; all treatment was useless, but warm turpentine fomentations gave great relief.

In relation to this case, Mr. Harrinson at a subsequent meeting mentioned as a fact of some interest that the nurse who attended this woman was seized with acute rheumatism with pericarditis, and died in a few days.

Dr. Gosset, repeated his observations in favour of bleeding. Mr. Walford said it was difficult to define what was truly meant by the term *puerperal fever*. He thought contagion might be taken as a test of the genuineness of the disease, and judged in this way; he was doubtful whether some of the cases reported by Dr. Wells were true puerperal fever; and he thought there was some inflammation in every genuine case.

At the next meeting the discussion was re-commenced by Dr. Gosset, who read some remarks from an esteemed author, (Mr. Hey, of Leeds,) strongly advocating bleeding and the antiphlogistic treatment.

Mr. Payne said Dr. Gooch had done the same thing, till from his ill success he was compelled to change his treatment.

Dr. Wells said that epidemics differed, one might require and bear bleeding, while another would not.

It was unanimously agreed that if bleeding were useful or necessary, it should be performed early.

On the 24th of April Mr. Shoreland read a lengthened and able paper, in which he endeavoured to prove the non-existence of puerperal fever as a specific disease. He said he had been led to doubt its existence in consequence of never having met with a case of it in the course of an attendance upon more than 500 women. He considered that after parturition females were liable to three distinct diseases, originating in extremely dissimilar causes, and he thought there was great impropriety in classing them under one denomination, to the confusion arising from which he attributed the varieties of opinion held upon the best mode of treatment, he therefore proposed to dispense with the term *puerperal* fever altogether, or to limit its application to one of the three. He considered the causes of these maladies were under our own control and easily obviated, and consequently that the very dangerous and frequently fatal effects ascribed to the puerperal fever, might be in a great measure, if not altogether, prevented.

Mr. Shoreland then described his first form as an infectious or typhoid fever, originating in a vitiated atmosphere, from overcrowding in lying-in hospitals, and a want of cleanliness in individuals in private

dwellings; but he did not conceive this to deserve the peculiar appellation of "puerperal," as it might attack other women, and even men. It was also obvious that its prevention was under our control.

His second form he described as a febrile affection, arising from irritation of the internal surface of the womb, and in a higher degree giving rise to inflammation of the substance. In extreme cases also the peritoneum became affected, frequently having a fatal termination. He proposed to call this *uterine fever*.

The third form had its origin in an irritated and subsequently inflamed state of the mucous coat of the intestinal canal, and might, with propriety, be denominated *enteritic fever*.

The causes of the last two were mechanical, and with proper care were easily avoided, and it was to the precautions which he used in his practice, (with a slight sketch of which he Mr. Shoreland favoured the Society,) that the exemption of his patients from this most formidable malady was to be ascribed.

Mr. Shoreland's plan was to remove the placenta early, within twenty minutes after the expulsion of the child, whereby he thought the pain of removal, and the chances of leaving any portion either of it or the membranes behind, to act as an irritant, were very much lessened. On the morning after delivery also he gave a dose of castor oil, and on the following day the action of the bowels was to be maintained by the following mixture:—Magnes. Sulph., dr. vj.; Pulv. Jalapæ, scr. ij.; Aquæ Menth. Pip., oz. vj., three tablespoonfuls to be taken every four or five hours. In this way the overloaded intestines were completely and easily cleared out, and the occurrence of irritation in them altogether avoided.

Before adopting this mode of practice the author had had his share of uterine febrile diseases, but since then, although he had attended many hundred women in the course of a very few years, no case had occurred to him.

Dr. Wells thought *puerperal fever* was the best term that could be employed as a *generic*, of which there were many species.

Mr. Payne persisted in his original idea of a *specific* disease, which was communicable from one to another.

Dr. Cowan said it was impossible to deny the existence of contagion, which was the inoculation of a morbid poison, and that every fever occurring in the parturient woman, and to which she was liable, from her peculiar condition, might be called *puerperal*.

Mr. Vines agreed in the notion of an independent form of the disease, which might arise from general conditions of the atmosphere or other circumstances. I do not think this the time to enter into an examination of the different views and opinions that have been held, but perhaps it may be thought, that to leave the subject where it is, is to leave it in rather an imperfect state; I will, therefore, simply add the opinion of Professor Murphy, of University College, in reference to the principal points at issue:—

First, then, in regard to the *identity of puerperal fever* and *puerperal* peritonitis, Dr. Murphy says:—"It is just as absurd to call puerperal fever attended with inflammation of the peritoneum puerperal peritonitis, as to name every case of pure peritonitis that is met with after delivery puerperal fever;" and after explaining the differences between them he says, "neither in the manner of attack, nor in the symptoms, nor in the morbid appearances, are puerperal fever and peritonitis perfectly alike."

Secondly. With regard to the *propriety* of bleeding he says, "Pure peritonitis occurring in the puerperal state must be treated on the same principles as when occurring at other times—antiphlogistically. Puerperal fever, with or without peritonitis, is to be treated by *evacuants* or *stimulants*, according to the dose of the poison, as evidenced by the pulse and system generally. if these warrant depletion, he considers it, when performed early, as a very efficacious remedy, regarding it in the light of an evacuant—as a means of getting rid of so much poisoned blood, rather than as an antiphlogistic; and where bleeding cannot be resorted to perhaps the other evacuants, as purgatives, emetics, diuretics, &c., will be of service. But where the dose of the poison has been excessive, evidenced by great prostration, *stimulants* alone will save the patient. Among these he enumerates camphor, eight or sixteen grains every four hours, opium to any extent short of narcotism; but the most efficacious he considers turpentine.

Thirdly. Dr. Murphy entertains a decided opinion that puerperal fever is a *specific* disease, arising from a specific poison, and as belonging to the class of zymotic diseases; arguing from its contagiousness, its epidemic and endemic influences, from its sudden approach and departure, its specific action on the serous surfaces, from its observing a tolerably regular course, and other analogies to recognised zymotic diseases; and that although analagous, yet that it is distinct from these diseases he proves by referring to its well-known characters, and to the fact that two of these diseases are often known to be in operation at the same time, while their individual identity is plainly preserved.

I beg to direct particular attention to the two following cases of albuminuria in the puerperal state, read November 28, 1840.

Puerperal Convulsions.—Mr. Harrinson first saw A. B., aged 31, October 20, 1849, being then eight and half months advanced in pregnancy. She had been seduced, and lately had suffered much distress of mind. She was slightly made, short, well formed, and was considered delicate. Since the period of quickening, had suffered from œdema of the legs without other inconvenience; but within the last two days the face had begun to swell, which was the reason of Mr. Harrinson's being sent for. The swelling of the legs and thighs had also increased to a great extent, and the urine had become scanty and high coloured. The urine on examination was found highly albuminous.

The next morning the convulsions commenced with a fit of fifteen minutes' duration, and was followed by insensibility, in which state Mr. Harrinson soon after

found her. The face appeared red and congested with livid spots, and there was a *tucking* of the eyes.

She was bled to twelve ounces, and a mixture of senna, tartarized soda, and antimonial wine, ordered every two hours. The convulsions, however, recurred, each lasting fifteen minutes, and between 10 A.M. and 2 P.M. she had five of them. Mr. Harrinson at this time finding the os uteri dilated to the size of a shilling ruptured the membranes and labour proceeding naturally, terminated in eight hours. During this proceeding she was slightly conscious and partly obedient to directions.

The next morning she was found in the same half conscious state, having passed a quiet night with no return of the fits. Pulse 120; the bowels had not been moved, nor urine passed since it was drawn off during labour. To continue the senna mixture.

Being much the same in the middle of the day, with the skin hot and dry, the tongue loaded with a white fur, the lochia though abundant, thick, and dark-coloured, and the general œdema but little abated, ten ounces of blood were taken from the loins by cupping, and the purgative continued.

In the evening the skin was moist, and three quarters of a pint of urine, thick and dark coloured, were drawn off. She was ordered three grains of calomel directly, lemonade with a little gin, and a mixture of hydriodate, bitartrate, and acetate of potash.

On the morning of the third day the bowels had acted freely, urine had been passed, and her expression and consciousness were improved, but by mid-day these secretions had begun to be passed unconsciously, the pulse had risen to 140—150, and the skin was very hot. In the evening she was low, restless, and muttering. Brandy and gin alternately, were ordered, and twenty *black drops* directly.

On the fourth morning she was found to have slept some hours; the skin was moist, and the pulse 100—120. No return of consciousness. In the course of the day there was incoherent muttering; the bowels were opened twice; and a pint and a half of urine drawn off by the catheter. Towards evening a severe pain in the bowels occurred, which was relieved by a profuse watery evacuation; the brain became much more confused, and the pulse very rapid. Opiate draught repeated.

On the fifth day she was reported very restless till three A.M., when she turned on her back, and still remains so. Eyes turned up, pupils contracted; tongue dry; face of a cyanosed lividity; subsultus; breathing stertorous; perspiration of an offensive urinous odour; slightly conscious. These extreme symptoms continued, more or less; slight epistaxis occurred; and the next morning she died.

Autopsy, eight hours after death. Abdomen only examined. Skin generally of a very dirty yellow colour, interspersed here and there with petechial spots and livid blisters. On opening the abdomen a very offensive penetrating odour escaped. There was about a pint of straw-coloured fluid in the abdominal cavity; peritoneum, intestines, &c., unaffected; uterus well contracted; no trace of inflammation; liver pale, mottled to some extent; external appearance of kidneys pale and mottled. On a section the cortical substance was found of a pale yellow colour, of homogeneous texture, and encroaching greatly on the tubular portion, which was also paler than natural. The veins were much loaded. A dirty yellowish fluid filled the infundibula and calices.

(The child was born asphyxiated; and, notwithstanding the persevering use of remedies, whereby he was somewhat recovered, ultimately died.)

Mr. HARRINSON then stated that he was not satisfied with the result of the treatment in this case; he thought bleeding was contra-indicated. He thought the convulsions, *per se*, had nothing to do with the fatal termination; she had only half a dozen, neither severe nor lasting. She was found stupified, and she continued more or less so till she died. It was not the stupor of congestion or coma, but of a *toxæmia*. After referring to the acknowledged ignorance of the profession of the pathology of this disease, Mr. H. proceeded to make some lengthened and most valuable remarks, the object of which was to prove that the blood in this disease was poisoned, at least in those cases accompanied by albuminous urine. He would not assert, however, that the albuminous urine, and consequent retention of urea, comprehended *all* the morbid elements of the disease. On the contrary, he was, I believe, rather inclined to the opinion that in the blood itself during pregnancy, especially during first pregnancies, there was generated a poisonous agent, of which the albuminous urine was perhaps only one of the occasional effects.

He considered, also, that, like other animal poisons, it may give rise to different effects in different individuals, under different circumstances and conditions. Thus, in one case giving rise to puerperal fever, in another to puerperal convulsions, in a third to puerperal mania. In confirmation of this view he referred to a case of Mr. Walford's, brought forward at the same meeting, in which a woman died of puerperal fever, who, on a previous labour, had had puerperal mania.

The inflammations arising in puerperal fever he thought analogous to those occurring in the course of Bright's disease, in purulent infection, in the latter stages of fever, in rheumatism, in syphilis, &c.; it was the same in puerperal convulsions. These so-called inflammations were "unhealthy inflammations," or rather irritations set up by the irruption of offending matters.

In considering how to guard against the effects of this poison, it was necessary first to be able to distinguish your cases. He was not prepared to say that albuminous urine necessarily accompanied this disease, but this condition of the urine was at present our only guide. Instead of short thick-necked women being the most liable to this disease, he was rather inclined to believe weak and cachetic constitutions as predisposing to it. In the treatment, therefore, he thought bleeding was not *the* remedy—in opposition to the uniform practice of all authorities, whatever their opinion of its pathology, the patient was struck with death by the puerperal poison, and to depress the powers by bleeding

was only to hasten the fatal end; however, he would not altogether condemn a moderate bleeding in some cases, and cupping to the loins was decidedly indicated. He was afraid of calomel; antimony seemed the most promising medicine; but laxatives, diaphoretics, and diuretics, were indispensable. Opium used judiciously was a *sine quâ non*. Nutriment and stimulants towards the end must not be forgotten. In short, the rationale of the treatment was to endeavour to eliminate the poison by every means short of exhausting the vital energies of the patient.

Mr. Walford thought there was no occasion to look for a general poison or one *sui generis* in this case; he considered the condition of the liver and kidneys sufficient to explain the toxic state of the blood, from the inability of these organs to perform the elimination allotted to them He did not disapprove of the treatment adopted.

Dr. Woodhouse did not think it correct to treat all cases of puerperal convulsions alike, and to say they all, *auctoritate medicorum*, are to be treated by bleeding. The condition and constitution of the individual should be taken into consideration. Puerperal convulsions occurred in the young, the robust, and the plethoric, as well as in the feeble and the anæmic. It could not be right to treat all these cases by copious bleedings. Dr. Woodhouse thought Mr. H.'s notion of poisoning a very valuable one, if proved.

Puerperal Mania.—Read March 27, 1850.—The subject of the following case had been a cook, and had been seduced. She was in the 40th year of her age; a strong, stout, full-blooded woman. For some weeks before her confinement Mr. Walford had been in attendance on her, and had detected that her urine was albuminous; there was also a tendency to excitement of the brain, evidenced by some slight convulsive fits, usually at bed-time, her mind, on account of her unfortunate condition, being extremely depressed.

Labour commenced on February 19th, 1850; its progress was very slow; the pains were lingering and tedious, and at the end of forty-six hours altogether disappeared, and violent mania supervened. Bleeding, tartar emetic, and other antiphlogistic means were resorted to, and in a few hours she was quieted. In consultation with Dr. Cowan, secale was then agreed on to be given, as the pains were returning, and the forceps to be used as soon as the perineum admitted of their application. After waiting three hours, Mr. Walford applied the forceps, but the mania soon returned, with great physical excitement, so that they were withdrawn, from the impossibility of keeping the patient still a moment. No advance being made in the labour, Mr. Walford, assisted by Mr. Harrinson, proceeded shortly afterwards to perforate the head, and the delivery was accomplished without further hinderance, within fifty-four hours from the commencement of labour. The child had been apparently dead some hours. The maniacal symptoms, however, continued unabated; and, notwithstanding the most diligent and attentive treatment, no impression was made on them, and she died on the eighth day.

Post-mortem. Brain large; vessels turgid with black blood; chest not examined; intestines healthy; kidneys large, and in the first stage of Bright's disease; left round ligament contained a fibrous tumour the size of a walnut; uterus soft and flabby; the placenta had been attached to the fundus; and here the lining membrane was in a sloughy state; the rest was healthy.

In reviewing the case Mr. Walford regretted the use of the secale, and that the perforator had not been used at an earlier period, so that the patient might have had the chance of escaping a fatal degree of cerebral excitement, so plainly reproduced by the labour pains.

Mr. Payne thought that after antiphlogistic treatment in these cases we should not interfere too soon, but give a dose of opium and tartar emetic, and be quiet for some time.

Mr. Harrinson said that this case supported the opinions he had advanced in a paper, read before the Society some months before, and which have just been detailed.

The two preceding cases of convulsions and mania have so many points of similitude, that although read at very different periods I have thought it well to class them together. Both had suffered much distress of mind; both had albuminous urine; both were advanced in years; both were first pregnancies; and both, I believe, died much in the same way: but in the one, convulsions was the leading feature, in the other, mania. How far the lesion of the kidneys is to be considered the primary or exciting cause of these various phenomena is a point which I must leave to the judgment of the Society. One thing seems certain, that the same predisposing causes, taking them altogether, produced very varied phenomena; neither am I myself inclined to separate any one cause from another as the most effectual; they are essentially a whole. That they are ordinary cases also we can scarcely allow; the second, indeed, is very exceptional to the usual setting in and course of puerperal mania; we should not, therefore, be justified in imputing all cases of mania and convulsions to one source; nor is it Mr. Harrinson's wish, I believe, to do so; but simply to establish the fact that the combination of albuminous urine with the noxious matter generated in the system in the puerperal state is a fertile source of convulsions, of mania, and of fever; the reason of the election in one case of one set of these phenomena, and in another of others, not being at all clear.

[To be continued.]

General Retrospect.

PRACTICAL MEDICINE AND PATHOLOGY.

Detection of Iodine in the Urine.

Dr. Dalton, (U.S.,) has experimented on the urine of patients who are taking iodine in medicinal doses. Becquerel concludes that it always appears in the urine, and detects it by mixing an emulsion of starch with

the urine, and afterwards adding chlorate of potass and sulphuric acid, by which process chlorine is set free, and, liberating the iodine from its compounds, allows it to strike a blue colour with the starch. In ordinary cases the addition of starch and nitric acid will suffice. The conclusions to which Dr. Dalton arrives, are :—

1. That iodine may appear in the urine thirty minutes after being taken, and may continue to appear for a period of twenty-four hours.

2. After a large dose taken for a long period, the time necessary for complete elimination is not proportionably increased.

3. It is, therefore, probable, that iodine does not accumulate in the system.—*American Journal of the Medical Sciences*, August.

On the power of the Cold Douche in promoting Absorption.—By Dr. Sloan.

The author's wish, in publishing his cases, is to call attention to a neglected means of treating tumours. The cases are three in number.

The first was one of encysted tumour in a male, situate on the sacral origin of the left gluteus maximus. It had existed for a long time, and was increasing in size. The douche was commenced September 6th, 1849, and continued till the 6th December of the same year. At this date the tumour was reduced to one-fourth of its original size.

The second case was a bronchocele, in a girl aged 20. After a long-continued treatment by iodine, it was submitted to the douche. Under this it diminished rapidly, but did not entirely disappear.

The third case was one of scirrhous mamma. The disease was in this case also partially absorbed.

The douche is applied by means of a gutta percha tube, applied to a water-main, or leading from a cistern.—*Edin. Month. Journ.*, December.

SURGERY.

Spina Bifida—Rupture of the Sac—Cure.—By Dr. Hance, (U.S.)

The subject of the case was a girl, aged 13. The tumour was situated at the juncture of the lumbar vertebræ with the sacrum, and when seen was as large as a quart measure. It was oval in shape. In 1848 the girl became the subject of measles, as a result of which the dependent portion of the tumour inflamed, and the integument sloughed, allowing the escape of the fluid. On the occurrence of the accident the general health suffered severely, the pulse became weak, and there was partial paraplegia. Soon the sac burst entirely, and its walls collapsed, after which they sloughed off, and healthy granulations sprung up under a tonic treatment and liberal diet. Eventually the discharge ceased, the sac gradually contracted until a semi-cartilaginous lump was all that was left to point out the former existence of the tumour. The girl has now become a woman, and is healthy and strong.—*American Journal*, Oct., 1850.

Ovariotomy.

The feasibility of the operation has again become the subject of discussion, having been mooted at the first meeting of the Medico-Chirurgical Society. It originated in the detail of the following successful case by Mr. Duffin :—

A woman, 38 years of age, having her abdomen enlarged to the size of the eighth month of pregnancy, this size having been attained in seven or eight months, and her general health appearing to be good, applied to the author for relief by operation. The rapid growth of the tumour, which appeared to be connected with the left ovarium, had been accompanied by neuralgic pains in the right thigh, in consequence of pressure on the sciatic nerve of that side. The tumour was very moveable, indicating the absence of adhesions. The patient was very urgent in her desire for the operation, and very confident that it would be successful, and it was accordingly performed on the 27th of August last by the author, assisted by Messrs. Fergusson, Ure, and Henry Smith, chloroform having been previously administered by Dr. Snow. The incision, at first of only sufficient size to admit the fore-finger for exploration, afterwards enlarged to three inches, was made in the linea alba, midway between the umbilicus and the pubes. The absence of adhesions having been ascertained, the sac was punctured by a trocar, and 130 ounces of a viscid, ropy fluid, of a light-brown colour, were let out. The collapsed cyst, containing a smaller cyst, the size of an orange, was drawn through the incision, and its pedicle secured by ligatures. The tumour was then separated, and the pedicle and ligatures were prevented from receding into the cavity of the abdomen by other ligatures attaching them to the wound. The ligatures came away on the fifteenth day, and the wound was healed on the twenty-second, the abdomen resuming its natural shape and size. The patient was kept on a light diet, took opium in sufficient doses for six successive nights, and the bowels were opened by enemata. On the eighteentth day she was able to get about a little. Her recovery is complete, and she has been able to resume the occupation of dressmaker.

This case was followed by a paper by Dr. Lee, giving an analysis of 108 cases of the operation. Dr. Lee commenced with the history of a case of ovarian dropsy successfully removed by a surgical operation, and reported in the *Edinburgh Medical and Surgical Journal* for 1822, by Dr. Nathan Smith, Professor of Physic and Surgery in Yale College, Connecticut. He then gives an account of an operation performed by Mr. John Lizars, of Edinburgh, in 1823, when *no* ovarian disease was found after the abdomen had been opened, and of three other operations by the same surgeon, when the diagnosis was more accurate, in 1825 and 1826; and of two operations by Dr. Granville in 1826 and 1827. He then refers to an operation performed in 1833 by Mr. Jeaffreson; and to three operations by Mr. King in 1834 and 1836. During the last twenty-seven years the operation has been attempted or

performed more than 130 times in Great Britain. Of 108 cases, of which authentic reports have been received, in 37 cases either no ovarian cyst or tumour to remove existed, or there were present ovarian cysts and tumours, the removal of which was found to be impracticable, and the operation was abandoned. Of these 37 cases, 14 died. The analysis given of 108 cases of ovariotomy, shows that in 37, or about one-third of the whole number, it was impossible to determine *previously* whether ovarian disease actually existed, or, when it did exist, whether its removal was practicable. Of the 71 cases in which ovarian cysts and tumours were removed, 24 proved fatal, in 14 of which the operation could not be completed. In the tabular analysis of the 108 cases appended to the paper, it appears that 45 cases are reported by Dr. Clay, and 11 by Mr. Lane; and to both these gentlemen the author expresses his thanks for the manner in which they have communicated to him the entire results of their experience of the operation.

Of the numerous speakers who recorded their sentiments on this occasion we select a few for notice.

Mr. Cæsar Hawkins had long doubted the propriety of extirpating diseased ovaries, and regretted that the profession, while fully aware of the successful cases, had not honestly been made acquainted with the failures. He also mentioned the significant fact, that ten hospital surgeons had performed the operation once, but none of them had done it a second time. Of these ten operations his own was the only successful one.

Mr. Phillips likewise condemned the practice of withholding the records of unsuccessful cases.

Dr. F. Bird spoke in favour of exploratory incisions, having made fifty such without bad results.

Fracture of the Thyroid Cartilage.—By Dr. Gibb.

The following rare case is published in the *British American Journal*:—

On the 1st of September, 1845, a healthy-looking man, aged about 30, was seen by Dr. Gibb, at the Montreal General Hospital, for symptoms connected with his throat. He stated that two or three days previously, when getting out of a carriage, he fell, and struck one of the steps near the wheel with the "bone of the neck," and ever since his voice has been imperfect, with, at the same time, a strange feeling about the throat. On examination Dr. Gibb found a longitudinal fracture through the pomum adami of the thyroid cartilage, the two ends of which could be moved upwards, and downwards, and in a direction from before backwards, producing a cartilaginous or soft crepitus. The deformity produced during this manipulation was trifling, and when the parts were untouched, the fractured ends were in the proper position. There was no swelling observable, and deglutition was not interfered with, although he had this peculiar indescribable sensation in the throat. There was not even any tenderness on a rough examination, and no appearance whatever of supervening inflammation. When speaking the voice was slightly rough and hoarse, and now and then whispering. In the treatment Dr. Gibb recommended the neck to be kept quite loose, and free from the use of a tight cravat or kerchief, a fluid diet, to abstain from conversation, and to maintain perfect rest and quiet.

Excision of the entire Uterus for Cauliflower (?) Excrescence.

The patient was a negro woman. The operation was performed by Dr. Eve, and successful, *quoad* the immediate result, but unfortunately a portion of the disease had been left behind, from the extension of which she died after four months.—*American Journal*, Oct.

Dislocation of the Great Toe from Bunion.—By Mr. Coulson.

At a meeting of the Medico-Chirurgical Society. Mr. Coulson called attention to the condition of the parts in this lesion. He showed that in some cases of bunion the great toe is twisted over or under the next to it; the ball of the toe becomes larger, the deformity increases, and the foot generally loses power. After a time the internal lateral ligament yields, then dislocation occurs, the bursa enlarges, inflammation and even ulceration follow, and the internal condyle of the metatarsal bone may pe exposed. On examining the joint the enlargement is found to be more apparent than real; the inner condyle of that bone always, and the outer often, project beyond the articulating surface of the first phalanx, the extent of the latter not being proportionate to that of the former. The articular surface of the metatarsal bone represents a pulley, with an elevated ridge in the centre. The axes of the bones do not coincide, so that a slight displacement induces great deformity. In very bad cases the articulating surface of the phalanx remains in the outer portion of the metatarsal bone; the synovial membrane is in some degree absorbed, the cartilages become thin and disappear, and the ends of the bones are eburnated. The specimens on the table illustrated these changes. The internal lateral ligaments were thinner than usual, and spread out, and absorption of the cartilages had commenced. With respect to the cause, Mr. Coulson stated, that wearing shoes had nothing to do with it; and he cited in proof the case of a mulatto who was nearly lamed by it, yet had never worn shoes. It has been said that the inner plantar ligament is pressed by the projecting downwards of the head of the astragalus, and that the ligaments of the toes, chiefly of the great toe, are thereby weakened, the bone itself being forced outwards by the oblique movement of the foot on the inner plantar surface; but Mr. Coulson could not see why the ligaments of the toes should yield, even if the calcaneo-scaphoid ligament were pressed upon, but was inclined to refer it to a giving way and weakening of the muscles acting on the great toe and metatarsal bone. The transverse and oblique muscles, he said, lose their power, the ends of the bones are not held together by them, the foot spreads and is deformed, the inner condyle projects, and the phalanges are carried outwards.—Reported in *Medical Times*, Nov. 16.

MIDWIFERY.

Hints on the Treatment of Lacerated Perineum.—By Dr. Horner.

Dr. Horner having a case in which the usual operation by paring the edges of the fissure had completely failed, determined on endeavouring to close the aperture by a plastic operation. He, accordingly, after placing the patient under chloroform, made two flaps from the perineum and vulva, one on the right and the other on the left, the base of the right flap being below, that of the left above. Upon crossing these flaps a partition was formed between the rectum and vulva, which was rendered permanent by fixing the flaps *in situ*, by interrupted stitches. For the first ten days success appeared certain, but subsequently it was found that the left flap had shrivelled, the right flap had also diminished, but still remained as a barrier between the two canals, and with a linen compress introduced into the vagina, so as to keep it in its place, the discharge of fæces was regulated so as to give but little inconvenience. On a later examination of the parts, they were found to be much improved. The traces of the operation had subsided, and there appeared to be a perfect division between the anus and vulva. The completeness of the union was, however, only external, as there was a small recto-vaginal fissure internally, which the author expected to overcome by a protracted use of caustic.—*American Journal of Medical Science.*

[This is the only instance, to our knowledge, in which autoplastic surgery has been made available in lacerated perineum, but it strikes us as a very feasible operation, and likely to be a good substitute for the tedious method of revivifying the lacerated edges in old cases.—Ed. P. J.]

On Chloroform in Midwifery.—By Dr. Beatty.

Further information on the value of chloroform in obstetrical practice has been afforded by Dr. Beatty. The result of his inquiries appears to be entirely confirmatory of the opinions put forth by Dr. Simpson, and he especially states, that when properly exhibited, no danger accrues either to mother or child. The reason why the parturient woman so seldom suffers from the use of chloroform in comparison with surgical patients, he states to be, in his opinion, that the former inhales it in the recumbent position, in which a minimum quantity produces the desired effects; and, secondly, that her stomach is seldom in a state of repletion—a condition which is now known to facilitate the occurrence of unfavourable symptoms. The grand desideratum, however, is the purity of the agent.

As regards its administration, Dr. Beatty informs us that he always uses a handkerchief. In ordinary cases he commences the inhalation when the os uteri is nearly dilated. In ordinary labour he never produces insensibility, but removes the handkerchief as soon as the breathing becomes sonorous. In this way the patient is never deprived of consciousness, but she is relieved from the severity of the pains.

The main object of Dr. Beatty's communication is, however, to show how chloroform may be used with advantage in lingering labours with inefficient pains, by combining its use with that of ergot. He narrates several cases in point, in which he first gave ergot to rouse the uterus to action, and then nullified the attendant pain by ordinary anæsthesia.—*Dublin Quarterly Journal*, August, 1850.

A BILL

FOR THE INCORPORATION OF GENERAL PRACTITIONERS IN MEDICINE, SURGERY, AND MIDWIFERY.

[Note.—The words printed in *Italics* are proposed to be inserted in the Committee.

Whereas, there are many persons practising the medical profession in England and Wales, not being of the degree of physicians, who combine the practice of medicine, surgery, midwifery, and pharmacy; and whereas all persons, other than physicians, who are desirous of becoming duly authorized by law to practice medicine, surgery, and pharmacy in England or Wales, are required to present themselves before the Royal College of Surgeons of England, for examination as to their fitness and capability "to exercise the art and science of surgery," and such persons (if they were not actually practising as an apothecary on the first day of August, one thousand eight hundred and fifteen, or have not acquired the right of practising as an apothecary by virtue of an Act passed in the sixth year of the reign of King George the Fourth, intituled "An Act to amend and explain an Act of the fifty-fifth year of his late Majesty, for better regulating the "practice of apothecaries throughout England and Wales)," are also required to present themselves before the Court of Examiners of the Master, Wardens, and Society of Apothecaries of the City of London, for examination as to their "skill and abilities in the science and practice of medicine," and their fitness and qualification to practise as an "apothecary," and such persons, upon obtaining the diploma of the said College of Surgeons, are "authorized to practise the art and science of surgery," and, upon obtaining a certificate of qualification to practise as an apothecary from the Court of Examiners of the said Master, Wardens, and Society of Apothecaries, are entitled to practise as an apothecary: and whereas very many persons who have obtained such diploma and certificate of qualification practise the art or science of midwifery; but no adequate provision has hitherto been made by law for ascertaining the skill and abilities of those who practise the said art or science: and whereas persons, not being of the degree of physicians, who have obtained such diploma as aforesaid, and have also obtained such certificate of qualification as aforesaid, or are otherwise authorized by law to practise as an apothecary, are known to the law as surgeons and apothecaries, and have also been heretofore commonly known and designated as "surgeon apothecaries," and have been of late years better known and distinguished by the name and title of "general practitioners:" and whereas the necessities of a large portion of the population of England and Wales imperatively require the existence of a

well-educated and numerous class of persons competent to practise all branches of the medical profession, and to minister to the sick in all emergencies: and whereas, in order the more effectually to promote and encourage the study of medicine, surgery, and midwifery, and to provide an adequate supply of such well-educated and well-qualified medical and surgical attendance for all classes of the population in England and Wales, it is expedient that the surgeon apothecaries or general practitioners should be united into one body politic and corporate, with power to appoint a Court of Examiners to examine all persons who shall hereafter desire to practise as "surgeon apothecaries" or "general practitioners," as to their competence to practise in that capacity, and to grant or withhold letters testimonial of the fitness and qualification of such persons to practise as surgeon apothecaries or general practitioners: and whereas there are now practising in England and Wales as surgeon apothecaries or general practitioners, divers persons who have obtained the diploma of the College of Surgeons of England, but who have not obtained a certificate of qualification to practise as an apothecary from the Court of Examiners of the Master, Wardens, and Society of Apothecaries, and are not otherwise authorized by law to practise as an apothecary in England or Wales, and divers other persons, who have obtained such certificate of qualification as aforesaid, or are otherwise authorized by law to practise as an apothecary in England or Wales, but who have not obtained the diploma of the College of Surgeons of England, and are not otherwise authorized by law to practise the art of surgery in England or Wales, and divers other persons, who are not authorized by law to practise either as surgeons or apothecaries in England, or Wales, but who are legally authorized to practise either as physicians, surgeons, or apothecaries, in some other part of the United Kingdom; and it is expedient that such several persons should, under certain restrictions, be admitted into the said body corporate: and whereas such incorporation whould tend materially to improve the status of the general practitioners, to supply the medical wants of a very large proportion of the rural population, and improve the sanitory condition of the working classes generally, by sending forth practitioners duly qualified by a general examination in all the several branches of medicine, surgery, and midwifery: be it enacted by the Queen's Most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, that the whole of an Act passed in the fifty-fifth year of the reign of King George the Third, intituled "An Act for better regulating the practice of apothecaries throughout England and Wales," except so much of the said Act as confirms such parts of the Letters Patent granted by King James the First, to the Master, Wardens, and Society of the Art and Mystery of Apothecaries of the City of London, as were not repealed by the said Act, but so as not to revive any Act or Charter repealed by the Act, be hereby repealed.

II. And be it enacted, that and now lawfully practising as surgeon apothecaries or general practitioners, and every person qualified as hereinafter provided, who, within the times respectively for that purpose hereinafter limited, shall cause his name to be enrolled as a member of the College hereby constituted, or who shall at any time hereafter be chosen as hereinafter mentioned, shall be incorporated into one body corporate and politic by the name of "The Royal College of General Practitioners in Medicine, Surgery, and Midwifery of England," and by that name shall have perpetual succession in all time coming, and shall and may sue and be sued, plead and be impleaded, in all courts, and before all justices and others.

III. And be it enacted, that the said body corporate or College shall and may have and use a common seal for their affairs, with full power from time to time, at their will and pleasure, to break, alter, or make anew the same.

IV. And be it enacted, that the said College shall provide and have a Common Hall in London or Westminster, or elsewhere, in the county of Middlesex, and shall at all times hereafter be capable in law to buy, take, hold, and enjoy, for their own use, any hereditaments, so that the yearly value of the whole thereof do not exceed five thousand pounds sterling at the time or several times of acquiring the same, and from time to time to sell, exchange, demise, and mortgage such hereditaments, at their will and pleasure.

V. And be it enacted, that the said College shall consist of an unlimited number of members, and shall be governed by a President and a Council.

VI. And be it enacted, that every person who was actually practising as an apothecary on the first day of August one thousand eight hundred and fifteen, or who before the passing of this Act shall have acquired the right of practising as an apothecary, by virtue of the Act of the sixth year of the reign of King George the Fourth, hereinbefore mentioned, and also every person who before the passing of this Act shall have obtained a certificate of qualification to practise as an apothecary from the Court of Examiners of the Society of Apothecaries of the City of London, and also every person at the time of the passing of this Act actually practising as a surgeon or apothecary, or practitioner in medicine, surgery, or midwifery, in England or Wales, being a fellow or licentiate or extra licentiate of any of the Royal Colleges of Physicians of England, Scotland, or Ireland, or a fellow, member, or licentiate of any of the Royal Colleges of Surgeons of England, Scotland, or Ireland, or a member of the Faculty of Physicians and Surgeons of Glasgow, or a doctor or bachelor in the Faculty of Medicine of any University of the United Kingdom of Great Britain or Ireland, shall be entitled, at any time within twelve calendar months next after the passing of this Act, if at the passing thereof he shall be resident in the United Kingdom, but if not resident therein at such time, and not of the class hereinbefore required to be actually practising in England or Wales at such time, then at any time within two years after the passing of this Act, to cause his name to be enrolled as a member of the said College, on payment to the said College of the fee of for the use of the said College, and on being so enrolled he shall become a member of the said College and Body Corporate.

VII. And be it enacted, that the names of all the persons entitled to enrol themselves as members by virtue of any of the foregoing qualifications who within the first calendar month next after the passing of this Act shall severally signify, in writing under their hands addressed to the registrar of the said College at the Common Hall thereof for the time being, their desire of becoming members of the said College, shall within the calendar month next ensuing the end of such first month be set forth on a schedule and one general diploma under the seal of the said College, which diploma and schedule shall be enrolled in the High Court of Chancery within *two* calendar months after the seal of the said College shall have been affixed thereto, and the order of the names contained in the said schedule shall be according to the priority of the dates of the several qualifications by virtue of which each person shall have been admitted a member of the said College, without discrimination of the several kinds of qualification hereinbefore enumerated; and in all cases in which the order of precedence of any names shall appear to the Council of the College to be doubtful, according to the foregoing rule, the doubtful matter shall be settled by the Council, either by lot or in such other manner as to the Council shall seem expedient; and the names of all the persons entitled to enrol themselves as members by virtue of any of the foregoing qualifications who in the course of the second and every following calendar month, until the end of the *twelfth* calendar month after the passing of this Act, shall signify their desire of becoming members as aforesaid, shall, within *one calendar month* from the end of each such month, be set forth in like manner in schedules to successive general diplomas of the like kind, each containing the names of all the applicants of that month, and each of which shall be enrolled in like manner in the High Court of Chancery within *two* calendar months after the seal of the College shall have been affixed thereto, and the order of the names contained in each schedule shall be settled in like manner as is provided respecting the names in the schedule to the first general diploma; and the admittance of every other member shall be by separate diploma under the seal of the said College, in such form as the Council of the College shall from time to time think fit and direct, which several diplomas shall bear date respectively at the time when the same shall be granted, but as respects those granted during the first two years before mentioned, shall only take precedence according to their respective priorities next after the general and special diplomas; provided always, that the special diplomas of every person entitled to enrol himself as a member by virtue of any of the foregoing qualifications who shall apply to be enrolled after the expiration of the said *twelve* calendar months, under favour of the extension of time hereinbefore granted to certain persons not resident in the United Kingdom at the time of the passing of this Act, may recite the date of the qualification by virtue of which such person shall be admitted a member, and the cause of postponement of the grant of such diplomas, and for all purposes of precedence or standing among the members of the said College all such members shall rank next after those mentioned in the said last general diploma, according to the date recited in such respective separate special diplomas.

VIII. And be it enacted, that, except as hereinbefore and hereinafter mentioned, no person shall become or be admitted a member of the said College until after he shall have attained the age of twenty-two years, and shall also have complied with such rules and regulations as the Council of the said College shall from time to time consider expedient, and by a bye-law or bye-laws direct, nor unless he shall have passed such examination or examinations as the said Council shall from time to time by a bye-law or bye-laws direct to be undergone by candidates for admission into the said College; but every fit and proper person, having attained such age, and having complied with such rules and regulations, and passed such examination or examinations, shall be entitled to be admitted a member of the said College.

IX. And be it enacted, that the fee to be paid on the admittance of every such new member as last aforesaid shall be any such sum not exceeding the sum of as the Council of the said College shall from time to time fix by a bye-law.

X. And be it enacted, that the Council shall have full power from time to time to admit into the said College as members thereof, without examination, but on payment of such a fee as they shall from time to time think fit, but which shall not exceed that which shall be payable by those admitted after examination; any person who shall have attained his age of *twenty-two* years, and shall be able to adduce evidence satisfactory to the Council that he has a medical or surgical degree, diploma, certificate, or license, from some University, College, or licensing body of the United Kingdom, duly authorized for the granting thereof, and that he has been engaged for at least *five* years in the course of professional study, embracing all the subjects on which an ordinary candidate for admission into the College would be examined, and also that the examination which he underwent was of a standard as high as that of the examination imposed by the College of General Practitioners on ordinary candidates.

XI. And be it enacted, that a register shall be kept by the Council of the said College, in a book or register to be kept for that purpose at the Common Hall of the said College, or at such other place for the time being as the said Council shall direct, of all persons who from time to time shall be so enrolled or admitted members of the said College as aforesaid, in alphabetical order, with their several places of abode and dates of their diplomas or letters testimonial, and also such other particulars, if any, as the said Council shall from time to time think it desirable to register; and as soon as conveniently may be after the expiration of *six* months from the passing of this Act the Council shall cause a copy of such register to be printed and published, and shall also in every subsequent year, in the month of January, cause a similar copy of such register to be printed and published, except as hereinafter restricted.

XII. And be it enacted that every person whose name shall have been so registered and published, and who shall be desirous that his name shall be continued in the public register, shall, in the month of November in every year, send to the Council of the said College

his name and place of abode, and change of residence, if any, with the date of his diploma or letters testimonial, or in default thereof his name shall be omitted by the said Council from the next published copy of the said register; and a printed copy of the said registry for the time being so published by or under the direction of the said Council shall be evidence in all Courts, and before all Justices and others, that the persons therein specified are duly registered under this Act; and the absence of the name of any person from such printed copy shall be evidence, until the contrary be made to appear, that such person is not registered under this Act.

[To be continued in our next.]

Medical Intelligence.

CHOLERA IN THE WEST INDIES.

Dr. Hector Gavin has been despatched by the Colonial Office to Barbadoes, to assist in the application of preventive measures against the spread of cholera. A better selection of a medical officer could not have been made.

HAGYARD *v.* COATES.

On the 19th instant, in the County Court, Bridlington, Mr. Hagyard, Surgeon, of Hunmanby, brought an action against J. Coates, for 15s., for attendance in midwifery upon his wife. The defendant pleaded his inability to pay this amount. His Honour, Judge Raines, inquired the usual amount paid by the Board of Guardians in cases of midwifery; and was informed that 10s. 6d. constituted the sum paid for confinements, without regard to distance, which induced his Honour to give a verdict of 10s. 6d. for the plaintiff. Although the plaintiff, a most respectable man, swore that Coates was able to pay the amount at once, the Judge directed him to pay 2s. a month; thus the profession will perceive that County Court law professes to regulate the charges of medical men by the "*penny wise*" folly of the Board of Guardians, and crowns the insult by the miserable and unnecessarily tedious manner in which the payments are made. It is high time that some legislative measure should be enacted to restrain the oppression which is daily victimising the honest practitioner from east, west, north, and south.—*Med. Times.*

PARISIAN MEDICAL SOCIETY.

At the meeting of this Society, held on Friday evening last, the following gentlemen were elected office-bearers for the next twelve-months:—J. W. Begbie, M.D., President; George Fleming, M.D., Vice-President; W. R. Sanders, M.D., Secretary; R. Sarell, Esq., Treasurer.

ROYAL COLLEGE OF PHYSICIANS.

At the quarterly meeting of the Comitia Majora, held on Monday, December 23rd, the following gentlemen, having undergone the necessary examinations for diploma, were admitted members of the College:—Dr. Roberts, Brook Street; Dr. Rutherford Ancram, Valparaiso. The following gentlemen were admitted extra-licentiates:—Dr. Brett, Southampton Street Mornington Crescent; Dr. Sullivan, Chili; Dr. Alexander, North Audley Street.

ROYAL COLLEGE OF SURGEONS.

The Council have appointed Mr. Highley, the eminent medical bookseller, of Fleet Street, to be the publisher and bookseller to this College.

Gentlemen admitted Members on Friday, December 13th, 1850:—John Craven, York; James Charles Dickinson, London; Joseph Earle, Grosvenor Street, West; Edmund Lord Hudson, Bacup, Lancashire; John Phillipson Langham, Forest of Dean, Gloucester; Henry Maund, Bromsgrove, Worcestershire; Ashley Greenough, Northampton; Francis Henry Plumptre, Queen Square, Bloomsbury; Alex. Myall Robinson, Newbury, Berkshire; Robert Rygate, Colet Place, Commercial Road; John Davis Weaver, Chester; George Webster, Dulwich, Surrey.

Gentlemen admitted Members on Friday, December 20th, 1850:—James Backhouse Bindloss; Thomas John Eames, Dorchester, Dorset; Alexander Carson, Colerain, co. Derry; John Gibson, Hackney; Fred. Hudson, Stockport, Cheshire; Nathaniel Walton Jones, Chichester, Sussex; Thomas John Jones, Amlwch, Anglesea; John Meane, Brighton, Sussex; Robert Roberts, Dyffryn, Arduduy, Merionethshire; Robert Sproule, Brockagh, co. Donegal; Robert Wall, Cork.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Thursday, Dec. 19, 1850:—Alfred Beekitt, Thorne; Robert Bolton; John Gabriel French, Burton-on-Trent; James Jerwood, Hereford; Robert Bohun Kidd, Norwich; John Morton, Norfolk; Robert Rooke Piance, Adelande; William Sutherland; Nathaniel Clement Wood, Norfolk; Nathaniel Stenson Wood.

OBITUARY.

In October last, at Peshawur, Dr. Lucas, assistant-surgeon of the 61st Foot.

December 6th, at Dunsford, near Exeter, T. N. Froom, Esq., surgeon, aged 35.

December 13th, at Edinburgh, John Philip, Esq., assistant-surgeon, R.N., the only surviving son of John Philip, Esq., surgeon, of Kirkcaldy.

December 14th, at Portobello, Dr. John Squair, late surgeon of the 8th Hussars.

December 24th, at Great Marlow, Bucks, William Hickman, Esq., in the 94th year of his age. The deceased was a pupil of the immortal Hunter, and had been in the active practice of his profession upwards of half a century; he died universally respected.

Lately, at Malvern, after a long and painful illness, in the 31st year of his age, T. S. Lee, Esq., formerly of Gordon Place, Euston Square. Mr. Lee was well known to the profession as the author of a work on "Uterine Tumours," which received a Jacksonian prize of the College of Surgeons.

Lately, in Jamaica, of the epidemic cholera, Drs. Bailey, Murcott, Tabois, and Tait, and Mr. Fagden.

ERRATUM.—In the report of the cases admitted under Dr. Nelson, at the Queen's Hospital, Birmingham, inserted at page 707 of last volume, line 33, for the "greatest bore," read the "greatest *bar*" that can present itself, &c.

TO CORRESPONDENTS.

Communications have been received from Mr. Stockwell, Dr. Robertson, Mr. Haggett, and Mr. Banks.

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho.

REMARKS UPON A

CASE IN WHICH THERE WERE EVIDENCES OF DILATED BRONCHI,

AND WHICH WAS COMPLICATED BY OCCASIONAL EXPECTORATION OF THIN, FIBRINOUS, CUP-SHAPED, FALSE MEMBRANES.

By P. MARTIN DUNCAN, M.D.,

PHYSICIAN TO THE ESSEX AND COLCHESTER HOSPITAL.

JOHN CLARK, aged 35, bricklayer, has always lived in Colchester, and has never had any serious illness before the commencement of his present malady. He has never had croup nor chronic cough, and he states that he has always lived steadily and soberly. Six years ago he had a bad cold, which confined him to his bed for five or six weeks; he has distinct recollection of having suffered from dyspnœa and difficulty of speaking, but antiphlogistic remedies do not appear to have been used with any degree of severity. A month after his convalescence, during which his lung symptoms appear to have left him, he was suddenly seized with pain in the right mammary region, cough supervened, and during a paroxysm of it he expectorated a light-coloured fibrinous mass, cup shaped, and much resembling in thickness and shape, the top of the thumb of a good-sized kid glove. During his illness, which lasted three months, he expectorated thirty of these false membranes; occasionally three or four were ejected simultaneously, but generally but one at a time was produced. For five years after this attack his health was good, neither cough nor expectoration of any kind were complained of, and he followed his usual avocations. At Christmas, 1849, he caught cold, and has not been well since. In April of the following year he experienced great pain in the right mammary region, it was attended by cough, considerable fever and dyspnœa. After suffering for several days repeated paroxysms of coughing, he suddenly spat up five of the before mentioned cup-shaped false membranes and immediately after a considerable quantity of scarlet blood. His urgent symptoms were immediately relieved, but in a few days they returned, and he then came under my care.

He is a tall well-formed man, thorax well developed, and measuring thirty-four inches in circumference beneath the clavicles. The general expansion during deep inspiration is deficient, his breathing being chiefly abdominal. The mammary and infra-axillary regions of the right side expand less than those of the left, but in no part is there perfect loss of motion.

Beneath the clavicles the percussion-sound is healthy, but on the right side, over the mammary, infra-mammary, and infra-axillary regions, there is considerable dulness. The left side of the chest is resonant throughout. The natural bronchophony is heard considerably to the right of the sternum, and in all parts of the chest, except in the right mammary, infra-mammary, and the infra-axillary regions, the true and healthy vesicular murmur is audible. In these regions there is a Babel of stethoscopic sounds. Tubular breathing, almost at certain spots taking on an amphoric character; loud, sibilant, and occasionally sonorous rhonchi, are heard low down posteriorly. In a spot little external to the right mamma, there was loud and tubular breathing during inspiration; a sharp "click" preceded the expiratory effort, which was accompanied by a distinct "burr." (After a fit of coughing which caused the expectoration of a very large false membrane, the sounds altered considerably in this spot. The tubular breathing was better developed, but the click and burr sounds were no longer heard. The voice, which was previously transmitted tolerably distinctly, now jarred the ear and produced perfect pectoriloquy.) The variations of the intensity with which the voice is transmitted through various parts of the infra-axillary region are very curious. In some spots the voice hardly strikes the ear at all, in others there are various degrees of pectoriloquy. There is no gurgling to be heard, and the expectoration is mucoid. He suffers slightly from dyspnœa and cough, but is never troubled by fœtid breath or disagreeably tasting sputa.

The cup-shaped false membranes vary in size from that of half a pigeon's egg to that of half a filbert. Their thickness is tolerably uniform, being about one-sixth of an inch; of a pale straw-colour; they are singularly elastic and resistent to the finger, their cohesion being as great as that of a pericardial false membrane of some weeks standing. Pure fibrin appears to be their principle component. The microscope discovered a few of the colourless cells of the blood, a few blood discs and numerous refractile granules, which, when aggregated, form the exudation corpuscle of Glüge.

These cup-shaped membranes were shrunken by the influence of dilute alcohol. The sputa usually expectorated, consisted of a glairy albuminous fluid holding ciliated and pavement epithelium cells, in mechanical suspension. He was ordered low diet Pil. Hydrarg., gr. iij.; Extr. Coloc. Co., gr. v. Fiat pil. ij,, o. n. sum. —R. Potass. Bicarb., gr. v.; Tinct. Hyoscy., min. xv.; Mist. Camph., oz. j., ter die.

May 11th.—Is better; stethoscopic signs the same. No expectoration. Pergat.

14th.—Has suffered from pain in the axilla for some hours. He has considerable dyspnœa, slight cough and much anxiety of countenance. No breath-sound is to be heard in the greater part of the infra-axillary region of the right side, and in those spots where tubular breathing was heard, neither it nor any other sounds any longer exist. Believing that one of his larger bronchial tubes was plugged up by one of the false membranes, I was about to order him an emetic, when a paroxysm of coughing set in, and five fibrinous cup-shaped membranes were coughed up. The tubular breathing and breath-sounds returned and were audible in the infra-axillary region, immediately after the expectoration of the membranes. In the evening he coughed up a little scarlet blood, and complained of much pain in the chest. Cont. Mist.—R. Pulv. Opii, gr. ½; Plumb., Acet., gr. ij., sextis horis formâ pil.

15th.—Is better.

16th.—Hæmoptysis stopped. Bowels constipated. Cont. Mist. Omit. Pil.

R. Hyd. Chlor., gr. j.; Pulv. Rhei, gr. x. Ft. Pil. iij. statim sumendæ.

17th.—Very much better. Bowels relieved. From this time he progressed towards health, gradually lost his cough, got flesh, and soon had appetite for full diet.

June 11.—His chest was examined before his discharge from the hospital. The dulness on percussion continues, but is more circumscribed; the tubular breathing is lessened in extent; all rhonchi and wheezing sounds have disappeared; pectoriloquy is audible here and there in the infra-axillary region of the right side, when a stethoscope with a small end is used.

August 1st.—Is in perfect health; the physical signs are still the same; he has neither cough nor expectoration.

It would appear, then, that our patient, a man of sober habits and apparently without any predisposition to chest affection, caught cold about five years ago and suffered for some weeks from bronchitis and some inflammatory attack about the larynx. A month after his convalescence he was seized with pain in the right mammary region, and during a fit of coughing expectorated a cup-shaped false membrane; his cough continued to annoy him for three months, and he occasionally expectorated three, four, or single false membranes, all cup-shaped and of different sizes. After the cessation of these symptoms he enjoyed nearly five years good health. At Christmas he caught cold, and after it had remained on him for four months he had another attack of pain, dyspnœa, fever, and cough, and expectorated numerous false membranes and scarlet florid blood. At the present time he is in good health, has neither cough, dyspnœa, nor expectoration of any kind. The physical signs determined that the lung in the mammary, infra-mammary, and infra-axillary regions of the right side was suffering from an altered state of its air-passages. Tubular breathing, almost at certain spots, taking on an amphoric character, was heard, and the voice jarred on the ear in those spots so as to give the notion of defined pectoriloquy. The normal bronchial sounds were heard far to the right of the sternum; and large sonorous rhonchi were audible low down in the infra-axillary region.

From these signs it is to be inferred that the main bronchial tubes of the lower and middle lobes of the right lung were more or less dilated; and that the more remote tubes were also dilated and occasionally sacculated. We have good evidence to the effect that the dilated bronchi were, and are now, sacculated. The cup-shaped fibrinous false membranes were evidently casts of the sacculi, and were analogous to, and probably formed in the same manner as, those tubular bronchial false membranes which occcasionally are seen by everybody. The false membranes ôccasionally were unable to pass through the lesser dilated bronchi, and impeded the passage of air into the air vesicles and bronchial tubes remote from the obstruction. It is to be noticed also that there was considerable disturbance of the bronchial mucous membrane during the illness, characterized by the expectoration of false membranes; for much mucous was secreted; and occasionally after the violent expulsion of the cup-shaped casts of the sacculi some blood was brought up. It would appear that the mucous membrane of the bronchial tubes secreted its normal product, whilst the sacculated dilatations eliminated a layer of pure fibrin. Before remarking upon the pathology of dilatations of the bronchi, it must be noticed that the stethoscopic signs of increased calibre of the bronchi, and of occasional sacculated projections from their interior, are still in existence, although the man's health is good, and he does not suffer from the cough and stinking expectoration of those affected with dilated bronchi.

Remarks.—The case recorded above presents several points of interest, amongst which those of dilatation of the bronchial tubes and fibrinous exudation from mucous surfaces are pre-eminent. Dilatation of the bronchial tubes, or bronchiectasis, appears to have escaped the notice of all writers before the great Laennec, whose history and pathology of the disease has been the thema upon which the variations of Andral, Stokes, Corrigan, and Hasse, of Zurich, have been founded. It appears to be a disease of tolerably frequent occurrence, and is well studied in children who have died from hooping cough; sufficiently rare for many years after puberty, it is occasionally found in the bodies of those dying from chronic lung diseases. The diseases upon which bronchiectasis is consequent are—chronic catarrh, bronchitis, tubercular disease, and pleuro-pneumonia. It appears to assume three forms; the first which I shall describe is a sequence of the last-named disease; the two other varieties follow after the three first diseases.

The first form of dilatation is that which is usually a sequence of pleuro-pneumonia; in it numerous bronchial tubes, sometimes every one in a lobe, are dilated along their whole extent; and the dilatation is greater towards the extremities of the tubes, where their structures are less dense and unyielding; the calibre of the tubes is greatly increased, occasionally to eight times its usual extent. The mucous membrane of the affected tubes is hypertrophied, thickened, and turgescent; it is occasionally elevated into highly vascular folds, and is usually covered with a thick muco-purulent secretion. The lower lobes of the lungs are those affected by this form; and when incisions are made into them the parallelism of the cylindrically-dilated bronchi is singularly evident. The proper parenchyma no longer exists; the air-cells in the neighbourhood of the bronchial tubes, which are nearly in close apposition, are obliterated, and a pale, flabby, soft tissue remains, being impervious to air and incapable of inflation. The dilatations end in blind sacs; the small twigs immediately supplying the intercellular spaces and the remote air-cells are obliterated. The cause of this obliteration is partly mechanical and partly attributable to vital changes. An old standing pleurisy may be cured, the fluid may be absorbed; but the lung may be found to

be unable to fill up the space occupied by the fluid, its power of expansion being lost on account of the alterations in the air-cells, consequent upon the pressure of the effusion and the loss of the exercise of their functions. One of two things, or both, must now occur; either the walls of the chest must be dragged in, or the calibre of the bronchial tubes must increase and gradually tend to the filling up of the vacant space, or both of these changes may happen. Inflammatory action in the mucous membrane would accelerate the bronchial dilatation by its paralysing influence upon the muscular fibres of the tubes. In long standing pneumonia the destruction of air-cells, consequent upon their infiltration by exudation of fibrin, is the first step towards the production of cylindrically-dilated bronchi; the subsequent contraction and atrophy of the infiltrated tissue produces a space which is required to be filled up by the neighbouring healthy air-cells, and if there be none, by the bronchi; in the one case emphysema, in the other bronchitis is the result. This kind of bronchiectasis is accompanied by excessive secretion from the mucous membrane of the tubes, generally speaking of a viscid tenacious mucus, and Laennec ascribes the production of the disease to the efforts employed for its expulsion. There can be no doubt but that when the remote causes of the dilatation are at work, such an excitant would greatly enhance the progress of the disease.

Hasse gives the following summary of the two other kinds of bronchiectasis; the first of these "exhibits a single point of one or another bronchial tube, mostly of the third or fourth order of magnitude, dilated into a cavity of more or less regularly spherical shape. In the majority of cases the walls are at the same time attenuated, the cartilages and the fibrous texture being for the most part stretched asunder, if not made to disappear altogether, and the mucous membrane changed into a thin, smooth, almost transparent pellicle. In the second form we find a *series* of these cystic dilatations, occupying the course of one and the same bronchial tube, which in the intervals retains its natural width. The attributes of this form, and especially the manner in which it originates, prove it to be but a variety of the first form; for in neither instance does the dilatation constitute the extreme end of a bronchial tube—that is to say, a *cul-de-sac*, but either allows the cylinder to issue from it again, in its normal calibre, for further distribution, or else opens with small orifices into the lesser bronchi beyond." These two kinds of bronchiectasis are the result of long continued bronchial inflammation; they are not attended by that destruction of the air-cells which is found in the form described as following pleuro-pneumonia, for the degeneration of the vesicular structure is only found in immediate contact with the cystiform dilatation. There must be a peculiar idiosyncracy in those who suffer from dilatation of the bronchi, for it does not follow upon hundreds of cases of chronic bronchitis, or upon the great majority of those diseases said to tend to its production. In the ordinary course of inflammation of the mucous membrane of the bronchial tubes, the capillaries in the areolar tissue beneath the basement membrane, which supports the epithelium, become distended, the current of blood is retarded, and the calibre of the vessels is irregularly increased; their office is suspended, they no longer give to the epithelium cells the wherewithal to produce the natural mucus. The air passages are speedily stripped of their epithelium and further changes ensue, exudation of the blood from the walls of the capillaries of the colourless pleura occurs, (occasionally blood corpuscles are set free,) owing to the aberration of the nutrition of the sub-basement tissues, the growth of the epithelium is rapid and irregular, and in those places where these cells are not reformed, a cell growth of a lower nature is produced—pus; or, owing to some peculiarity, no cell forms are produced, and the fluid whence they ought to have been formed is simply poured out, it is by nature spontaneously coagulable and consists of fibrin and more or less albumen. It is tolerably evident that an exudation of such a fibrinous mass would tend to plug up a smaller bronchus, and that it would be assisted in doing so by the mucus and pus also secreted. A certain amount of bronchial tube would be then exposed to the distending effects of muscular action upon retained air, and bronchiectasis may ensue; or the plug might simply cause the collapse of the neighbouring air-cells and consequent partial dilatation of a near bronchial tube.

These mechanical cases are, however, only the stimuli to a series of perverted vital actions; simple distension by accumulation of secretion will not of itself cause dilatation of gland-ducts; for instance, it merely acts as a stimulus to an irregularity of growth; the dilatation may be accompanied by hypertrophy or by atrophy of the structures implicated. In the case before us there was a series of sacciform dilatations, and the calibre of the bronchial tubes between the dilatations was also increased, so that there was a combination of the varieties of the bronchiectasis—an union of that variety characterised by simple cylindrical, and of that characterised by a series of cystic dilatations. It is tolerably evident that in this case the dilatations were occasionally cylindrical, and that at other spots the dilatation did not affect the whole bronchial calibre, but that a lateral dilatation occurred constituting a greater or less lateral cul de sac. The physical signs and the negative evidence proved that the fibrinous, cup-shaped, false membranes, came from the lateral sacciform bronchial dilatations, and the long attacks of bronchitis from which the patient suffered accounted for the formation of the alterations in the calibre of the bronchial tubes. It would be out of place to do otherwise than simply mention, that bronchitis is met with, in all its forms, in the lungs of those dying from phthisis pulmonalis, and that it occasionally effects a cure.

The subject of bronchial false membranes—polypi as they were formerly called—is one of great interest; for an excellent sketch of the bibliography of the disease I must refer to a paper by Dr. Ranking in this journal, (June 13th, 1849, p. 316,) but I am not aware that a case in which the false membranes were cup-shaped has been recorded, unless the case of Phericides, mentioned

by Hippocrates, in which γαλακτωδεα were expectorated, was one. We are all familiar with the false membrane of croup, and the exudations of certain forms of laryngitis, such as occasionally occur in measles and scarlet fever. False membranes are also found, under certain circumstances, in the fauces, on the schneiderian membrane, in the œsophagus, stomach, certain portions of the intestinal canal, biliary passages, tubuli uriniferi, ureters, urinary bladder and urethra. Exudative processes in the uterus, fallopian tubes, and vagina, are constantly presented to our notice.

Were we to say that all mucous membranes are capable, under certain circumstances, of producing false membranes, we should be pretty well correct. They are most commonly seen in the throat and air passages. Rokitansky gives an excellent description of the disease as found in the other mucous membranes. But as Dr. Ranking remarks at the conclusion of his capital paper:—"But why fibrinous rather than mucous secretion should take place, remains a mystery." In one organ, the kidney, simple inflammation invariably produces casts of the uriniferous tubes—transparent, fibrinous, microscopic effusions, which exactly correspond with the inside of the affected uriniferous tubes—in no other organ is this the case. There is more required than that aberration of nutrition which we call inflammation, to replace the mucous secretion by a fibrinous exudation.

An experiment by J. A. Albers, does not really, although it seems to do so, militate against the opinion. He excited artificial inflammation in the air-passages of animals, and produced fibrinous false membranes. It must be noticed, however, that brute pathology is hardly to be identified with, or to be argued upon like, that of man; and the manner in which he produced his inflammatory effects, tended to cause great effusion of blood into the parenchyma and into the smaller bronchi. Its coagulation would account for what he describes as spurious membranes. It is also notorious that acute bronchitis, or in fact any simple inflammatory attack of a mucous membrane, excepting in the kidney, is very rarely indeed accompanied by the formation of false membranes. But during certain epidemics of measles, and not in those characterised by great malignancy, tubular expectoration from the air passages is common. There is a note to a passage in "Hasse's Pathology":—"The most strongly marked case I ever met with of tubular expectoration from the trachea and bronchi, occurred during the prevalence of a very mild epidemic of measles." In mild cases of scarlet fever, however, membranous exudations on the fauces and larynx do not occur; they are only found in cases characterised by their peculiar malignancy. The tough plugs found in mucous canals after their exposure to corrosive agents, are not fibrinous exudations, although if these masses of mucus, coagulated serum, and blood, be removed, and the patient recover from the immediate effects of the injury, the damaged mucous membrane is very liable to produce fibrinous layers instead of mucus, (epithelium, &c.,) for some time. Many forms of croup and of exudations in the œsophagus, stomach, and intestines, never occur as primary affections, but according to Rokitansky as *sequelæ* of exanthematic processes, in variola, in typhus, in the absorption of pus into the circulation, and particularly in puerperal inflammation of the uterine veins. He has also observed, with great care, the varieties of exudation in the uterus in puerperal fever, and describes with his usual minuteness the exudative processes in the mucous membranes consequent on the puerperal poison.

It would appear, then, that certain diseases which originate by the absorption of a poison from without, or by the formation of noxious matter within a cavity, and their consequent absorption, predispose to fibrinous exudation from mucous membranes, and that certain poisons produce false membranes in the bronchial and tracheal mucous membranes, whilst others affect the genito-urinary and digestive mucous tracts.

Where we cannot trace the presence of a poison, and where there are structural changes in the mucous membrane affected with the the fibrinous exudation, it must be admitted that structural changes tend to the production of false membranes; but the absence of these in most cases, where the calibre or the nature of the mucous tube has undergone a change, forces us to believe, that either idiosyncrasy or a peculiar state of the mucous membrane with which we are unacquainted, has much to do with this production.

Cases occur in plenty where idiosyncrasy appears to be the cause of the replacement of a mucous by a fibrinous secretion.

The circumstances under which mucous membranes pour out a fibrinous product, which coagulates and forms a false membrane, exudation or polypus, are when the system is influenced by—

1. Idiosyncrasy.
2. Idiosyncrasy; structural changes.
3. Morbific agents in the circulation, (pus, typhus, measles, scarlet fever, poisons.)
4. Simple inflammation.

It is, of course, implied, that there is an exciting cause to enable the two first influences to act, as hyperæmia, of greater or less intensity. The toxic agents carry with them the power of inducing certain kinds of inflammation.

I may here remark, that in my experience cases in which bronchial false membranes, (I allude especially to those which plug up the various ramifications of a third or fourth rate bronchus,) have been expectorated, run a very peculiar course, and rarely terminate fatally. Death generally is caused by the effects of occlusion of the affected bronchi, and need not happen for many years, the patient being carried off by emphysema and dilated right side of the heart. Intensity of inflammation does not seem to have any thing to do with the production of false membranes, nor can we take refuge under the explanation of its occurring as an effect of some peculiar irritation, for by doing so we only transfer our difficulty.

We know nothing concerning the state of the blood in this disease, and cannot imagine that even a highly fibrinous condition of it could produce aught but a tendency to the exudation. From what I have noticed,

I am inclined to believe that before a fibrinous exudation can occur, the epithelium of that part of the mucous membrane covered by it, is destroyed, and that the basement membrane, and the vessels of the areolar tissue beneath it, are all that remain of the mucous membrane. The areolar tissue is invariably infiltrated with serum, and the whole tissue is softer than usual. This is notably the case in the exanthemata. Occasionally the fibrinous exudation extends from one spot, whence it arises, and covers the surrounding mucous surface.

As a rule, when the epithelium is removed from a mucous membrane, the vessels of the areolar tissue beneath the basement throw out the colourless blood plasma as usual, and pus cells are formed for a while in it; subsequently the normal mucous cells are developed. We must account for the production of false membranes instead of mucus or pus, by supposing there is an inability on the part of the blood plasma to develop cell life; it coagulates rather, and forms a fibrinous mass. The circumstances producing the above inability, and tending to the primary destruction of the epithelium, are those, then, which I have mentioned as being of four kinds.

In the case recorded at the commencement of this paper, the formation of false membranes covering altered tracts of mucous membrane was constant; and as now, none have been expectorated for many weeks, it may be supposed that epithelial cell growth is formed from the blood plasma, and that the sacculated dilatations are now covered by a healthy mucous membrane. Nature seems to have done everything in this case; the few doses of acetate of lead were required to control a slight hæmorrhage from the bronchial tubes, excited as much by the presence of passing false membranes as by the exertions employed to get rid of them.

CASES OF OVARIAN DROPSY.

By JOHN GRANT WILSON, Esq.,

LATE SENIOR-SURGEON TO THE BRISTOL GENERAL HOSPITAL.

Read at the Quarterly Meeting of the Bath and Bristol Branch, Dec. 19, 1850.

The attention of the medical profession being at this time much directed to the subject of ovarian disease, and many of the leading men amongst us appearing still to differ in opinion as to the extent of surgical interference admissible in such cases, I consider it the duty of every surgeon to record those cases which have occurred in his practice, where operations have been attempted for the radical cure of ovarian dropsy, and to report faithfully the result of each case, whether favourable or unfavourable.

Influenced by this consideration I have thought it right to lay before this meeting a brief account of four cases of ovarian dropsy, treated by me since October, 1849, and to detail a mode of operating which differs, in some important respects, from any hitherto described, and which, unless I am mistaken, will be found to be attended with less risk than any hitherto made public.

Previous, however, to describing this particular operation, I will briefly notice my first case, in which a cure was effected by the formation of an oviduct, (as this process has been called) by means of a caustic issue. The case stands thus in my note book:—

Elizabeth Antrobus, aged 38, spinster, consulted me in October, 1849, with an ovarian tumour, which had reached an inconvenient size, and which she wished to have tapped. I had tapped her twice before—the first time in October, 1840, when three and a half gallons of opalescent dirty-looking fluid were evacuated. The cyst refilled slowly, not requiring to be emptied again till May, 1845, at which time a smaller quantity, (not quite two gallons) of similar looking fluid was drawn off. The cyst again filled slowly. An interval of four years and seven months had occurred between the first and second tappings, and now an interval of four years and five months passed before she again sought relief in that way.

As her health had been remarkably good during the whole of both intervals already named, much better indeed than it had been previous to the first tapping, I thought it a fair case to try to effect a radical cure, and, having been favourably impressed by the reasoning adduced by Dr. Tilt, in recommending the treatment of these cases by caustic issue, I proposed that proceeding to my patient, and having obtained her consent, proceeded to carry it into practice on October 29th. Selecting a spot about two inches below the umbilicus, in the median line, a stick of potassa fusa was rubbed upon it, over a space about the size of a shilling. A portion of Vienna paste was then applied to the same surface, and confined by lint and plaster, and allowed to remain until the next day, by which time an eschar was formed, not much less than half a crown in size. The eschar proved very deep, and did not require to have the caustic renewed, but it was eight weeks before it separated sufficiently to discharge the water. At first no injection of any kind was used, but in three or four weeks from the evacuation of the water the discharge became purulent and fœtid, and my patient's health declined so rapidly that I feared I should lose her. Under a generous diet, with quinine internally, and the repeated injection of the cyst with warm water, she rallied, after having lain a month or six weeks longer, in a very precarious state. At that time a weak solution of iodine, (one drachm of the compound tincture to six ounces of water,) was occasionally used, without producing any ill effect, and a portion of gutta percha tubing was fitted to the opening of the wound. This was fitted with a wooden plug, so that the discharge could be drawn off at stated times. Before this the wound showed a disposition to close permanently, and required to be opened by a probe, to evacuate the fluid that accumulated, the patient always suffering until this was done. From the time the gutta percha tube was introduced, and the iodine injection used, the cyst began to contract, and the patient to improve

steadily, and this continued until she has now got quite well. The tube remained in four or five months, and was then removed. I have recently seen her, and there is still a small fistulous opening, not quite closed; through this you may pass a small probe, to examine the cyst, which may be said to be quite contracted, as the probe will pass in no direction beyond half an inch, and as she has gained flesh and strength, and has been enabled for some time to resume her usual habits, I think I am justified in calling it a cure, though I should scarcely be disposed, except under peculiar circumstances, to recommend a repetition of the treatment, as it was not wholly free from risk, and the progress of the case was very slow.

My second case occurred in August last. The patient, Mary Ann Pidwell, aged 24, had been a lady's maid, and, during the illness of her mistress, four years before, had lifted her, and felt at the time, as she describes it, a strain on the right side of the bowels; an enlargement soon showed itself, which had, latterly, very much increased. At the time of consulting me she measured forty-four inches in the girth at the umbilicus, was thin, but not emaciated, and the characteristic shrinking about the shoulders and the upper part of the chest, was very marked. The fluctuation was very distinct, and equally perceptible over the whole tumour. She had never been tapped, had menstruated regularly, her general health was good, her habits regular and simple, and she had had no inflammatory attack during the whole time. These circumstances induced me to consider this a favourable case for attempting a radical cure by an operation which much thought and a careful consideration of all the published cases of ovariotomy I had met with, had suggested to my mind, as being likely to effect the purpose at much less risk than those I had seen described; accordingly, having stated the case fairly to my patient, setting the risks on one side, and the advantages on the other, and having obtained her consent, I performed the operation on the 20th of August, assisted by my friend and former colleague Mr. Lang, Surgeon to the Bristol General Hospital, Mr. Martin, Surgeon to the Bristol Dispensary, another professional friend, and my own pupil. The principles of the operation were—

1st. To make as small an incision as possible.

2nd. To draw out only as much of the cyst as could be extracted readily, and without displacement of the other contents of the abdomen.

3rd. To endeavour to keep the wound always filled with the cyst, so that neither *air* nor *fluid* should be admitted into the cavity of the abdomen.

4th. To cut off the cyst, *not* close to the wound, but from one and a half to two inches beyond it, so that when the portion of cyst has been removed, the cut margins could be carefully examined, and the vessels secured.

5th. To secure each vessel on the cut margin of the cyst separately by a fine silk, and to cut off both ends close, so as to have no ligature hanging from the wound.

6th. To close the external wound as quickly as possible.

According to these principles I proceeded to operate. The patient was brought to the foot of the bed, opposite a good light, and placed under chloroform. I made an incision two and a half inches long, commencing two inches below the umbilicus, and half an inch to the right of the median line, to which my incision was parallel. I carefully dissected through the rectus muscle and its sheaths to the peritoneum, which was opened and divided on a director. The white shining cyst was then laid bare, and each respiration showed such free and independent movement of the parietes over the cyst as to confirm my hope and expectation that no adhesion existed.

The next step was to introduce a long needle through the cyst at right angles to the wound, so as to keep the cyst up to the upper angle, whilst the fluid was evacuated by introducing a trocar at the lower angle of the wound. This was done and thirty-one pints of remarkably clear, limpid, and colourless fluid were drawn off. The effects of the chloroform had now passed off, and were not renewed. A portion of the cyst, forming a bag eleven inches long and fifteen inches wide, was then removed by the scissors; there was free bleeding from various small arteries at the surface, each of which was separately tied, care being taken that the ligatures included both layers of which the cyst was composed. The number of the ligatures was as many as thirteen. The remainder of the cyst was then returned into the abdomen, and the wound closed with three sutures; and a circular bandage having been applied, the patient was placed in bed.

During the evening of the operation there was frequent sickness and vomiting, and opiates given by the mouth seemed rather to increase this. There was very little tenderness on pressure, and the pulse was moderate.

21st.—(The day after the operation) the sickness and vomiting continued, with flatulence. Creasote mixture seemed to control the sickness for a time, but it returned.

The 22nd was also an anxious uncomfortable day. She had obtained little or no sleep since the operation, and the sickness recurred at intervals; still the pulse was moderate, the urine not high coloured, no great abdominal tenderness existed, and the countenance was not bad. The marked features of peritonitis were absent. Small doses of sulphate of magnesia were ordered in a weak infusion of gentian; this seemed to allay the sickness for a time, but the bowels acted rather too freely, and the creasote was renewed, with small doses of tincture of opium.

23rd.—Has had a restless night, but as the day advanced she became more composed. Pulse 96. The wound appeared healed for two-thirds of its extent. Towards evening much uneasiness returned, with vomiting, and the bowels seemed irritated. An opiate injection was given, with forty minims of the tincture of opium; this produced a good night, and the vomiting ceased.

24th.—Appeared much better. The opiate injection

was repeated, and continued for several nights. She took more food and retained it.

25th.—A purulent discharge took place from the lower part of the wound, which was ordered to be poulticed. This continued for several days; but she seemed in other respects improved.

29th.—The discharge had ceased, and she had improved greatly under a more generous diet and small doses of quinine.

September 3rd.—There seemed a swelling about the wound, and some uneasiness. The pulse rose to 110. Upon opening the adhesion at the lower part of the wound, by a probe, a discharge of pus took place, which at once relieved the symptoms. Poultices were again ordered. The discharge continued four or five days, the abdomen again became flat, and the wound finally healed on the 8th of September, after which there was no untoward symptom to report. She was able to leave her bed fifteen days after the operation, and at the end of three weeks she took exercise in the open air. She has continued quite well ever since, and has gained flesh, especially about the neck and shoulders, and upper part of the chest. She says her health is better and she can do more than she has done for many years.

My next case is as follows:—

Sabina Adams, aged 39, spinster, has had ovarian enlargement for six years, commencing first on the right side. She has never been tapped, and although not robust has never had any inflammatory attack, or serious fit of illness during the growth of the tumour. She measured forty inches round the abdomen. She consented to submit to the operation for radical cure, which accordingly was performed on the 25th of November, in the presence of Dr. Budd, three of the surgeons of the Bristol General Hospital, and Mr. Martin. Chloroform was administered as in the previous case, and the steps of the operation conducted precisely as on the former occasion. The fluid was equally clear and limpid, a smaller portion of cyst was removed, and ten ligatures were used to secure the small bleeding arteries. The remainder of the cyst was returned, and the wound, (which was even smaller than the last,) closed by three sutures. From the very first there was no bad symptom; opiates were well borne and acted admirably in soothing; flatulence was the only thing that caused annoyance. The wound quite healed on the sixth day, there never was any purulent discharge from it, or anything to interrupt the favourable progress of the case. About the ninth day some little feverish disturbance took place, the exciting cause of which did not seem very apparent, at all events it subsided on the eleventh day, and her convalescence was uninterrupted, although slow. She is now quite well.

My last case, I am sorry to say, was not so fortunate in its termination, although to me it has been a most instructive one, and though fatal in its termination has tended still more to confirm me in my preference of the principles of the operation I have previously detailed.

Mrs. Maria Gibbons, aged 45, wife of a farmer, had been married twice, had had seven children and one miscarriage. She first perceived the ovarian enlargement after the birth of the fifth child; the two last children she carried whilst the tumour was in progress. She was tapped in March, 1848, nearly two years after the birth of her last child. The quantity of water drawn off was not known; it was believed that the tumour was entirely emptied, and no swelling was perceptible after the evacuation of the fluid. She was a tall woman, with large bones, but with little flesh. She measured forty-five inches round the body at the umbilicus. She had formerly attended the Bristol market, and although the fact was concealed from me till after her death, I have since learned that she was addicted to drinking spirits—not to excess, but habitually.

As there did not appear at the time any reason to prohibit the operation, which, from hearing of the two former cases, she was very anxious to submit to, I determined to accede to her wishes, and on the 25th of November, in the presence of Dr. Symonds, Mr. Bartrum, my friend Mr. Lang, and three other surgeons, I proceeded to operate. Chloroform was administered, which, however, did not act well, making her restless, and after the first incision it was not continued. The early steps of this operation were the same as the two former cases. The length of the incision was two inches and a half. The cyst was exposed. No adhesion were detected anteriorly, and the needle being introduced at the upper angle of the wound, the trocar at the lower, as before, twenty-eight pints of clear limpid fluid were drawn off. During the evacuation of the water she became very faint, although pressure was carefully kept up by the abdominal circular bandage. This faintness continued, and obliged us to give her brandy, and in the efforts to tighten the bandage, the needle at the upper part of the wound was displaced; however, the cyst was easily drawn forth by a hook forceps, although it did not come out so readily and evenly as in the two former cases. Although no adhesion existed anteriorly, yet the cyst was bound down at the posterior and upper portions; when, therefore, the necessary traction was used in drawing it through the wound, the lower portion connected with the broad ligament was disproportionately drawn up, and this, from losing the needle, which serves as a land-mark, I could not so well perceive.

As soon as the cyst began to be drawn forth two remarkable bands were perceptible on its anterior surface, seeming to be duplicatures of the external layers. These (as it was afterwards found) contained many considerable blood vessels. As soon as I had drawn out as much of the cyst as would readily come forth, although that was a much smaller portion than had been removed on the former occasions, I placed a temporary ligature around the whole, to prevent the portion of the cyst which was not to be removed from slipping back into the wound when the separation of the other portion took place. Although this precaution was used, as soon as I divided the cyst, that portion where the two bands already alluded to were situated, slipped from the temporary ligature and escaped into the

wound, and the vessels it contained gave rise to hæmorrhage; for it was a considerable time before this cut portion could be found and brought again out of the wound, so as to enable the vessels to be secured; and as there was great difficulty in arresting the bleeding by putting ligatures on each vessel separately at this part of the cyst, I was compelled to deviate in this instance from one of the principles I have considered essential in my operation, and to apply a strong ligature around the whole of that portion. This thick portion might at first sight have been taken for the pedicle, but it was not so in reality, as will be shewn presently.

The strong ligature, applied as I have above stated, was effectual in restraining the bleeding. The remaining portion of the cyst was carefully examined along the whole margin, and each bleeding point secured by separate ligatures, including both layers of the cyst, as on the former occasion. These were cut close, but the strong ligature around the thick portion was left long and brought through the wound. The operation was then concluded as in the preceding cases, care being taken to press out from the wound all the blood that had escaped into the cavity of the abdomen, previous to the insertion of the sutures; a broad bandage was then applied, and the patient put to bed. She was very faint and low; she had never fully recovered the faintness which came over her when the water was drawn off, The loss of blood and the weariness of so tedious an operation had depressed her so much that nearly twelve ounces of brandy were administered to her during the operation. Immediately on her being placed in bed an anodyne draught, with forty minims of tincture of opium, was given, and she was left. Four hours afterwards I again saw her. She was lying in a state of stupor, though she replied when spoken to; she complained of no pain. At ten at night I found her much in the same state. Pulse about 100; surface warmer; still complaining of little or no pain. A smaller opiate was given her.

26th.—In the morning she appeared better than could have been expected; she had slept nearly all night. She had lain a good deal on her side, and some serous discharge had taken place from the wound, but not to any extent. She complained very little, but had passed no water. Pulse 110. It was still deemed advisable to keep her under the influence of opium; and in the interim a draught was given, containing one drop of Fleming's tincture of aconite.

Middle day.—She had passed water; complained a little more; pulse about the same; had taken very little since the operation but a little gruel and a cup of tea; countenance looked sunk and somewhat anxious.

Evening.—Pulse 90, and she appeared rather more composed, but looked haggard; less weeping from the wound.

27th.—She had again slept much, and made little or no complaint; her pulse was moderate, ranging all day rather below 90; she was thirsty, but did not care to take any nourishment—it was difficult to induce her to take even gruel and tea; her countenance did not look comfortable, but she had no positively bad symptom; no sickness, no shivering, and very little pain; she passed water more freely.

28th.—She has not passed so good a night; looks more anxious, and complains of more general uneasiness; pulse in the morning still moderate, about 90. An enema of warm water was given to move the bowels, but returned without effect. As the day passed on she complained of sickness, and brought up her medicine; she also complained of shivering, but no decided rigor. A discharge of bloody serum took place from the wound in the evening, and she vomited some dark coloured fluid from her stomach. A castor oil enema was given, which also failed, and three grains of calomel were then administered and the opium suspended.

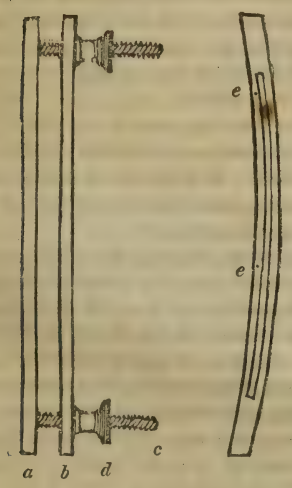
29th.—She passed a restless night, and was certainly worse this morning. No motion; vomiting of dark fluid still continued; pulse 120. The calomel was repeated, and small doses of Epsom salts given. Towards evening there was a small motion, and the vomiting was checked for a time, but the pulse increased in frequency; the bowels became distended and tympanitic; and she was evidently losing ground fast.

She died on the 30th, and twenty-three hours after death I examined the body in the presence of Mr. Lang and Mr. Martin. The abdomen was distended with air, and there was also a considerable quantity of bloody serum in the cavities of the abdomen and pelvis. Extensive peritonitis existed over the whole contents of the abdomen and pelvis, and this was especially manifest in the course of the strong ligature, its track being also marked with pus. The thick portion was seen to be an offset from the broad ligament, close to the fundus uteri, but was not the main pedicle of the cyst, being connected only with the anterior wall. The cyst was attached along the remainder of the right lateral ligament, and had adhesions posteriorly to the mesentery and meso-colon. That portion of the cyst where five ligatures were applied, was certainly less inflamed than any of the parts concerned.

There can be no doubt that death in this case resulted from peritonitis, brought on partly by the hæmorrhage which took place into the cavity of the abdomen at the time of the operation, and partly by the large ligature, which was obliged to be applied round the root of the anterior bands already described, and which I was obliged to leave suspended through the external wound. It is true that, added to these causes, my patient was addicted to the habitual use of ardent spirits, and therefore it is probable I might have lost her, had I even been able fully to carry out the principles of my operation in her case; still, as I was compelled by unforeseen and untoward circumstances, to deviate from those principles, I have no doubt that inasmuch as I did so, insomuch did I lessen the chances of success. However disappointed and mortified, therefore, I may feel at the result of the case, I am not disheartened, for I cannot consider it otherwise than a confirmation of the views which, from the first, I entertained concerning the principles of the operation, and which I so fully verified in the two former cases.

The case, moreover, has taught me many useful lessons, whereby I hope to profit, should I again be called upon to perform a similar operation; and I will now describe an instrument which I would strongly recommend to be used in all operations of the kind, as a means not only of effectually preventing the cut portion of the cyst from slipping back into the wound before the vessels are secured, but of facilitating all manipulations which may be necessary to be performed on the remaining portion of the cyst previous to its being returned into the abdomen. A sketch of the instrument is given below, which, on inspection, will render the use at once evident. *Fig. I.* *a b* are two semi-cylindrical pieces of box-wood, seven inches long; these, when placed in apposition, form a slightly-curved cylinder, the end of which is half an inch in diameter. A brass screw *c*, furnished with a thumb-screw *d*, is fixed to each end of *a*, and passes through a corresponding hole in *b*. The branches of the instrument can thus be entirely separated, or they can be screwed closely together, so as to hold anything between them very firmly. *Fig. II.* gives another view of the instrument, which shows that it is slightly curved to adapt itself to the convexity of the abdomen, and there is also a slit *e e* on the side of the branches, which adds to their lightness, and gives them a firm grasp of any soft slippery body like an ovarian cyst.

Fig. I. *Fig. II.*



When the water is evacuated, and the cyst drawn forth from the wound, one of these branches should be applied on each side of the cyst, and then screwed up so as to hold the cyst firmly between them. The cyst thus secured may be next cut off with a pair of scissors, an inch beyond the part where it is embraced by the instrument; the cut margin may then be carefully examined, and each bleeding point secured with great ease, the instrument in every respect serving the office of a tourniquet, and by preventing anything like slipping, enabling you to include both layers of the cyst in the ligatures, which I consider important, as the two layers will then most readily unite, diminishing the cut surface exposed, and thereby lessening the risk of inflammation.

In conclusion, I think I am fully justified in recommending this operation as one simple in its nature, and easy of performance—as one more free from risk than any hitherto performed, and applicable to all cases where the contents of the ovarian cyst are fluid only, uncomplicated with solid enlargement of any kind, whether malignant or not, and, fortunately, these constitute the majority of cases we meet with. Should even adhesions exist to an extent which renders it impracticable to remove more than a small segment of the cyst, this plan of operation will enable that segment to be removed with comparative safety, and with every prospect of perfect success; I therefore cannot but hope that it will be sanctioned by the approval of many who object to the more formidable operations hitherto proposed, and by becoming more generally known and practised, it may be the means of saving the lives of many whom the fear of greater danger would cause to sink, *unrelieved*, into an early grave.

THREE CASES OF OVARIAN DISEASE.

ONE OPERATED ON—FATAL.

By THOMAS G. STOCKWELL, Esq.,

SURGEON TO THE EASTERN DISPENSARY, BATH.

Read at the Quarterly Meeting of the Bath and Bristol Branch, Dec. 19, 1850.

Hannah Hiscox, aged 20, unmarried, a servant, had always enjoyed good health until the age of 16, when she suffered severely at each menstrual period. About September 12, 1848, she perceived a tumour in the right iliac region, which caused no pain, but increased rapidly in size, and she became unable to use any exertion without becoming immediately faint. She applied for admission into Guy's Hospital, where the tumour was pronounced to be ovarian, and the operation of extirpation was proposed, which her friends dissenting from, she left the hospital. A very severe attack of pain occurring in the right side, she was admitted into the Bath United Hospital, under Dr. Clarke. This attack was of long continuance and the pain very severe; upwards of fifty leeches were applied, but she was discharged still increasing in size. She then came under my care as a patient at the Eastern Dispensary. Her general state of health was then good, although she suffered from severe pain, accompanied by evident enlargement of the tumour at each menstrual period. The abdomen measured about forty-four inches at the umbilicus. The tumour appeared moveable, and could be slightly drawn upwards without affecting the uterus, which was but little displaced, the os being directed a little more backwards than usual; it was uniformly globular; its contents evidently fluctuated, and the skin of the abdomen moved freely over its anterior surface. Mr. Crouch, of Bruton, saw the patient at

this time and was of opinion that the operation could be undertaken with a very fair prospect of success. The patient herself earnestly requested its performance although perfectly aware of its danger, as she was unable to earn her livelihood, or even move at all without great exertion and distress. On Thursday, November 14, the operation was performed, with the assistance of Dr. Davies, Mr. Stockwell, sen., Mr. Bartrum, and Mr. Brace. The patient being under the influence of chloroform, and the room heated to about 75° Fahrenheit, an incision was made from immediately below the umbilicus to about an inch and a half above the pubes, the peritoneum divided to about the same extent, the tumour punctured and emptied with a large catheter. As it decreased in size it was withdrawn from the abdomen, the walls of the cavity being pressed together prevented any exposure of the intestines. There was no adhesion whatever, and the pedicle, which was very small, was transfixed by a double ligature and tied, the ends of the ligature were fastened externally, the wound closed by two sutures and some adhesive straps; there was scarcely any blood lost. In the course of the afternoon she suffered a good deal of pain at intervals, which was quieted by two grains of opium. The pulse rose to 120; she had passed water, had some sleep, and in the intervals between the pains was perfectly easy. At night the pulse was down to 100.

15th.—Has had a good night; was sick once; pulse 110; tongue moist; skin perspiring; pains much less frequent during the night. Seven P.M., has only had one attack of pain to-day, which came on when passing water; pulse 130; tongue moist; no general tenderness of abdomen.

16th.—Has had a good night; this morning a little feverish; pulse 120; tongue moist; skin perspiring; no pain on pressure of abdomen, except immediately over the pedicle; complains of much inconvenience from flatulence, which is confined to the stomach. Through this day the pain continued, and sickness came on, which at five P.M. was almost constant; she became very restless; pulse 160; countenance pinched; whole abdomen distended with air; general soreness; not increased on pressure. At eleven P.M. the sickness ceased for about an hour, when it returned and continued without any intermission until about three A.M. During the vomiting about two or three ounces of dark-coloured fluid escaped from the lower angle of the wound; the pulse rapidly became weaker, and she died at ten A.M. on the morning of the 17th.

Post-mortem examination twenty-six hours after death.—The wound was united throughout its whole extent sufficiently firmly to prevent the escape of the air with which the peritoneal cavity was distended. The peritoneum was found inflamed for about half an inch on either side of the incision, and upon the anterior surface of the uterus a thick layer of lymph was deposited, the posterior surface was only slightly reddened; this membrane in every other part was healthy, and there was no fluid whatever in its cavity. That which escaped from the wound during the act of vomiting, had come from a cavity formed round the pedicle by the adhesive inflammation, glueing the uterus and pedicle to the abdominal parietes close to the wound, and completely separating the pedicle from the general cavity of the peritoneum. The tumour arose from the anterior and inferior part of the ovary on the posterior surface of which was a recent corpus luteum. It was composed of a very thick fibrous coat, covered by peritoneum, loosely attached, so that it moved very freely over the inner fibrous layer; it contained one smaller cyst about the size of a walnut, and in the pedicle a great number of smaller cysts about the size of peas were found. The sac contained about eleven pints of thick yellowish fluid.

During the last year and a half two other cases have come under my care; the first, which was fatal in about four months, occurred in a woman, aged 48, married, having had four children, she had suffered from dropsy of the ovary nearly two years. She was tapped four times, an interval of about six weeks intervening between the first and second tappings; on both which occasions about eighteen pints were evacuated from a single cyst. An equal quantity of fluid collected in a shorter period previous to the third tapping. At the last tapping I was not present, but was called to her a few nights after, and found a portion of the sac, about four inches long, and one in thickness, hanging from the small wound made by the trocar, and a large quantity of fluid was escaping through this accidentally-formed oviduct, and continued to do so until her death, which occurred in about three weeks. The fluid was not purulent but always of exactly the same character as that withdrawn from the cavity by the trocar, she dying of the exhaustion consequent on the continuous albuminous secretion.

The second case was also a married woman, aged 54, with a family, who had been dropsical three years. The abdomen was of an enormous size. She was only tapped once, the fluid collected again in less than a month, and the patient died.

On examining the body, the ovarian cyst was found to have a few not very extensive adhesions to the abdominal parietes, and to two or three folds of the small intestines. The sack was in some part of its anterior portion an inch and a half thick, in the posterior portion not quite so thick. It consisted mainly of one cell, with the exception of two smaller ones in the posterior inferior part, containing the same yellowish fluid as the larger sac. The pedicle was large and broad, and from the weight of the attached ovary had dragged out of the pelvis the uterus and other ovary, which was natural. This patient died from exhaustion, caused by the disease, not from any surgical interference. The rapidly fatal termination of these two cases, had much weight in deciding me on the admissibility of the operation in the first-mentioned case, as I thought that she being only 20, and otherwise of good constitution, was justified in encountering the risk.

[The two last cases were not mentioned at the meeting.]

Provincial Medical & Surgical Journal.

WEDNESDAY, JANUARY 22, 1851.

ALTHOUGH, as we have stated in our last number, it is not our habit either to glorify ourselves upon past proceedings, or to offer a tempting bill of literary fare in reference to the future, for which, were we so inclined, we have the precedent of several of our cotemporaries; we do not think it inconsistent with our position as Editors of a journal, untramelled by trade, to pause awhile on the threshold of the new year, and ere we consign to oblivion that which has just closed over us, to glance backward upon the career of the medical profession in its various aspects, during that lengthened period.

The first topic which courts a retrospective notice might naturally be that of Medical Reform; but on this point we must not dilate, as anything like a discussion of the subject is considered to be unsuited to our pages. We may, however, remark, that as regards any satisfactory adjustment of the several grievances, real and imaginary, under which we labour, the final event seems to be as distant as ever. The miserable class jealousies which disgrace our ranks appears to act as an effectual barrier to any legislative interference.

Quackery stalks throughout the land with as unblushing a front as ever. As if there were not "pathys" enough already in existence to fool Her Majesty's lieges to the top of their bent, the past year has been distinguished by the introduction of another under the name of "kinesopathy," which professes to cure all diseases by exercise and gymnastics. There is at least this to be said in favour of the new system, that it is not like its cousin German homœopathy, altogether opposed to common sense.

Something has been done during the year that is gone to enhance the social position of medical men, a thing in truth very much needed. The military Order of the Bath has at length been conceded, or rather wrung out of those in authority, who should not have needed agitation to induce them to gratify the justifiable pride of men upon whom depends the health and lives of our country's defenders. Most cordially do we congratulate our military brethren upon this acknowledgement of their rights, although certain kind friends at one time thought fit to insinuate that we were luke warm upon the subject.

To our naval friends also we beg to offer our modicum of felicitation. There appears at length to be some prospect that men of education, as Naval Assistant-Surgeons now claim to be, will in future be emancipated from the cockpit and its nuisances. The mistaken self-importance of superior office may at first render this concession almost nugatory, but we doubt not that naval medical men will be ere long treated as gentlemen, in spite of quarter-deck vulgarity.

In matters of science, the past year has not much to boast. We have had no discovery to emulate that of chloroform. One of the most striking circumstances which has transpired has been a crusade against the use of the speculum, as subversive of good morals, and as a mistake as regards uterine pathology. We have already expressed our opinion on this extraordinary movement, and therefore need not repeat it. Similar and more reasonable criticism has been brought to bear upon the operation of ovariotomy, to which, since chloroform has been introduced, there seems to be too great a proclivity among those who think to *cut* their way to the Temple of Fame. Our last number contains a record of a case by Mr. NORMAN, which we would commend to the careful consideration of the chivalrous incisors of the female abdomen. If such men as our talented and experienced associate are foiled in their diagnosis, younger surgeons may well pause before they undertake so formidable an operation.

The only subject of interest in the department of pure surgery during the past year, is that of the perineal section in urethral stricture. The question of the propriety of this operation seems still to be *sub judice;* and we therefore refrain from expressing an opinion on the matter. We only venture to hope that any further discussion between gentlemen occupying a high professional position, will not be defaced by the outpourings of personal animosity.

Our therapeutical resources have been but little added to. The introduction of the "kousso" in the treatment of tænia, being the only novelty we can call to mind, which has fully realised the character with which it was brought before the profession.

We may thus observe that the past year has not been signalised by any marked results, either as to medical science or medical politics. We

are told, however, that during the present year the bright dreams of Medical Reform are destined to be accomplished. It may be so, but we doubt the fact. In the mean time, there is a reform equally necessary to the welfare of the medical republic, which each of us may accomplish—that of his own heart. We can all find something more to learn ourselves—something that should claim our charitable consideration in others; we can all endeavour to stifle the jealousy, the love of detraction, the "envy, hatred, malice, and all uncharitableness," for which our profession is proverbial. If we do this, our individual happiness, and our collective prosperity will be more advanced, than by clutching at the moonshine of professional titles, and hoping upon such flimsy advantages alone to achieve a social position, which, after all, the discerning portion of the public will accord only to *integrity* and *knowledge*.

Reviews.

Of Happiness in its relation to Work and Knowledge. An Introductory Lecture delivered before the Members of the Chichester Literary Society, October 25th, 1850, and published at their request. By John Forbes, M.D., F.R.S., Physician to Her Majesty's Household. London: Smith, Elder, and Co. pp. 75.

We are always glad to meet Dr. Forbes in print, as we never miss finding that freshness and originality which spring from an honest, vigorous, manly, outspeaking, and fully-accomplished mind. He tells you what he has actually thought, observed, practised, felt, not merely what he thinks ought to be thought, done, and suffered, so that, agree with him or not, you still have the conviction that a real man is before you. On this account his style is excellent, as he knows what to say, and expresses it in the clearest, simplest words. There is neither dulness, affectation, nor pedantry in him. This essay is one of particular interest, as it is autobiographical. One who has had a happy life, looks back with an honest self-satisfaction at his own prosperous career, and out of his long experience he points a moral for the benefit of his juniors. He has actively employed his mind, and he tells the young that there is a great happiness in this work. The argument he uses is, that, the due exercise of every faculty of the body is, (owing to the goodness of God,) a source of pleasure, and the same holds good of the mind, so that by duly employing the intellectual faculties, we insure ourselves a large amount of enjoyment. We must refer our readers to the work itself for the manner in which this is worked out. They will find it full of matter, well and closely and convincingly argued, copiously illustrated, abounding in that practical wisdom which is the fruit of a life both active and contemplative, and, withal, relieved from dryness and dreariness by its spirit, and by that light with which the cultivated imagination illuminates and beautifies whatever it touches. For, amidst the practical duties of our unimaginative profession, Dr. Forbes has not neglected the due culture of his imagination.

His conclusion is so full of true feeling and affection, and so admirably and tersely expressed, that we should quote it, did we not wish, for their own sakes, to make our readers procure the essay for themselves. The substance is, "I have had a happy life, so happy an one that had I the option I would live it again willingly, with Franklin's proviso, of correcting in the second edition a few errors of the first; and I attribute my happiness to my healthy frame and sanguine temperament;—to my want of patrimony compelling me to exert myself;—to my birth in a country where education was valued;—to my profession, which diligently exercised my mind;—and to my father, who had the wisdom, the courage, and the exceeding love, to bestow all that could be spared of his worldly means, to purchase for his sons that which is beyond price—education."

The thought which arises on reading such a fair picture of health and prosperity is,—But how is this example applicable to the unhealthy body, or to the dark side of life;—to those born with melancholic or nervous temperaments, with irritable nerves, with weak solar plexuses, with vile cachexias, with black bile corrupting their crimson blood, who are so organized that they rarely know what that pleasure and comfort means which is the rule of healthy sanguine natures;—or, what is more, who have shattered their bodies by their own vices or imprudencies;—or, again, to those who have failed in life, who are suffering from the *res augusta domi*;—or to those who are the martyrs of spiritual combats, of whom Luther, Bunyan, Baxter, and not Franklin, are types? Will it even apply to the sanguine happy man when laid aside by disease, when withdrawn by old age from the activities of life, when

robbed by circumstances of all outward means of pleasure? For to him is specially applicable the wise caution:—"Call no man happy until he is dead." The letters of Southey, *the* man of this century, who most assiduously cultivated his intellect throughout his life, and who gained much happiness from it, show that in his sorrows he could not rely on work, but on his hope of immortality.

Happiness is, after all, the principal object in the life of every man. If present comfort and enjoyment in this life is alone intended, then the due and normal use of the faculties of the body and of the mind produces that enjoyment, and the individual has his immediate reward. But the happiness which embraces this world and another, and which is the only happiness worth seeking by a being endowed with the power of looking before and after, is alone to be procured by regulating the normal exertion of the bodily and mental faculties, according to the laws of Christianity, by submitting the human will to the divine will, as revealed to us. Otherwise the man may be merely an epicurean, living for the largest amount of immediate bodily or mental gratification, with no reference to another stage of being. Dr. Forbes, of course, alludes to this, but passes it over as belonging to the province of the divine. Happiness however is, we conceive, one of those subjects in which there is no marked decision between the provinces of the physician, the moral philosopher, and the divine; and it seems impossible to treat it satisfactorily, unless we regard it as embracing the whole man—physical, intellectual, and spiritual.

We cannot conclude without expressing our earnest wish, as well as expectation, that Dr. Forbes will continue to enrich our literature, and in this way to elevate and adorn our profession. He is one of those who, by occupying waste minutes and half hours, have always time, even in the busiest periods of life; and with a healthy and vigorous body, and an active mind in the fulness of its mature powers, he has none of the excuses for rest which so often cripple the deeds of feebler organizations.

Proceedings of Societies.

READING PATHOLOGICAL SOCIETY.

THE RETROSPECTIVE ADDRESS,

DELIVERED AT THE NINTH ANNIVERSARY OF THE READING PATHOLOGICAL SOCIETY, JULY 24TH, 1850.

By CHARLES H. GAMBLE, Esq.,

Diseases of the Reproductive System.*

Hysteritis, &c.—On the 27th February, Mr. Jeston, jun., read some notes of a case of diseased uterus, accompanied by violent hysterical symptoms, in a young woman. There was feebleness of pulse throughout. The hysterical movements on attempting to touch the abdomen were so violent, that no examination of the belly could be made. The hysterical paroxysm he had reason to believe was sometimes feigned, and there were grounds of suspicion that drugs had been given to produce abortion. The case was afterwards the subject of a coroner's inquest.

After death the small intestines were found inflamed, the peritoneun covering the uterus was gangrenous, the right ovary had been converted into a complete bag of pus, and the fallopian tube and body of the uterus as well as its walls contained pus. The fundus was enlarged and the neck shortened, and the uterus was considered to present all the appearances of having been impregnated.

Mr. Jeston, sen., said the symptoms were so peculiar and violent that they gave him the idea of an overdose of colchicum having been taken.

Mr. Vines said that he had lately had a case somewhat similar, where there had been violent hysteria; the symptoms were at length all relieved by the discharge of pus from the vagina. There had been no suspicion of pregnancy.

Retention of Dead Ovum.—On the 27th March, Mr. Walford related the case of a woman aged 40, and the mother of a large family, healthy and active, who had experienced symptoms of pregnancy for four months, when they ceased; the catamenia, however, did not return; and she went on some months longer ere a discharge took place from the vagina, which continued some time, an entire ovum being at length expelled. The embryo was that of about four months, the placenta was rounded, the size of a pear, dense, and hard in structure.

Mr. Walford believed the state of the placenta to have been the cause of the death of the fœtus. In an answer to a question to Mr. Harrinson, he said he believed the ovum to have been retained *nine months*.

* Concluded from page 22.)

Tedious Labour.—On the same evening Mr Jeston, jun., related a case of tedious labour occurring in a woman, aged 33, with her first child. The pains were frequent but inefficient, and some doses of secale that were given had no effect. The discharges became very offensive, and by introducing a tube into the uterus he drew off about a pint of a very offensive fluid, and a quantity of fœtid air, which expelled the liquid some feet from the side of the bed. Delivery was at last accomplished by the forceps. The child was dead, but the mother made a good recovery.

Polypus Uteri.—On the 31st October, Mr. May presented a specimen of fibrous polypus of the uterus, which he had lately removed from a lady. The usual pathological symptoms had been exhibited, and the tumour presented the (common) anatomical characters. Its removal had been effected by the scissors, in the same way as one which he placed in the museum some time ago, and which was of a precisely similar character. This was the seventh case Mr. May had seen, two of which he had removed by excision. Mr. May then alluded to the mode in which these tumours affect the system, and described their varieties. The two specimens then on the table he considered identical with fibrous tumours of the uterus. There was another form of vascular tumour, generally growing from within the os, easily broken down and bleeding very much, which usually yielded to *caustic*. There was also a third variety of tumour, which could scarcely be called polypus, as it was not pedunculated, and this kind was generally intimately connected with the vascular system of the uterus, exhausting the patient by hæmorrhage if not removed.

Mr. May thought the pedunculated tumours most easily removed by the scissors or knife, and the operation was rarely unsuccessful. The cases treated by ligature ran the risk of putrid absorption.

Surgical Diseases.

Inflammation of the Longitudinal Sinus.—On the 6th June, 1849, the late Mr. Dunn presented a portion of the calvarium of a young woman aged 21, who had come into the hospital for a tumour of the scalp, of doubtful nature. An exploring puncture was made when a sanious discharge took place of more than the contents of the tumour, and which was suppressed with difficulty. After a few days violent epistaxis occurred, not easily restrained. About the fifth or sixth day erysipelas of the forehead and eyes appeared, which was cured by caustic; to this cerebral symptoms succeeded and she ultimately sank.

Autopsy.—The bone underneath the tumour was found carious to the extent of half-a-crown, and having small points on its surface. The disease was situated over the centre of the sagittal suture. The tumour communicated with the longitudinal sinus by four small openings, two were evidently congenital, being perfectly smooth and round, and gave passage to two small veins; the other two were smaller, uneven, situated on the centre line, and were the effects of ulceration. The sinus was vascular (?) for two inches, and completely blocked up with fibrin.

The brain appeared quite healthy, but the veins of the surface were much congested.

It was conjectured that the epistaxis and the following erysipelas were due to the blocking up of the sinus. In an irregular discussion which followed, Mr. May expressed an opinion that it was a case of phlebitis of those two veins extending to the longitudinal sinus, causing the effusion of lymph within that sinus, and producing the epistaxis and erysipelas.

In connection with this case Mr. Shoreland mentioned that a soldier once presented himself to him with a tumour of the scalp which he opened and gave vent to some gelatinous puriform matter, and supposing it to be an encysted tumour, he put some red precipitate into it with the view of causing its ulceration. After a few days he was surprised to find a portion of the outer table, and ultimately of the inner table, exfoliated, leaving a cavity of the size of a crown, which ultimately healed by granulations, and did well.

Mr. May further said, the practical inference to be drawn from Mr. Dunn's case was the proneness to phlebitis in certain low states of the system, whether in the uterus after childbirth, or in the veins elsewhere from operations, and in such state nothing ought to be attempted without great caution.

Suicidal Wounds.—On the 4th July, 1849, Mr. May exhibited Dr. Marshall Hall's tracheotomy instrument, and read a case from the *Provincial Medical Journal*, in the minutes of the Birmingham Pathological Society, from some points in the treatment of which he dissented and contrasted it with the treatment of a similar case that he had in the hospital under his care. (The Birmingham case is published in the Journal for May 2, 1849.) Mr. May thought there was an error in attempting to pass an œsophagus tube, and secondly, in not making an opening in the trachea. In his case the suicidal wound passed through the thyro-hyoid membrane to the pharynx; the wound had been partially closed by two sutures at the sides, but any fluid attempted to be swallowed came out at the wound. He had the patient placed in a comfortable position so as to keep the edges of the wound in apposition with a piece of gauze over it. No fluid or food was given for twenty-six days, and she was nourished by injections of strong beef-tea, about a quarter of a pint being thrown up the rectum every four hours.

Mr. May thought this case very important, as shewing the power of sustaining life by that mode for such a length of time, and he considered it too much lost sight of in our medical practice. The bowels were gently moved by injections of thin gruel, but this he was not very anxious about. The patient suffered slightly from thirst, but did not emaciate at all, or very slightly. The urine was regularly secreted, and was quite natural. She went on to recovery without any unpleasant symptom. In connection with this mode of nourishing patients Mr. May referred to the case of

a lady, where obstruction existed in the upper bowels, who was kept alive for several days by beef-tea injections; at the same time also she suffered from exhausting diarrhœa, but strange to say, the beef tea never returned. Mr. May concluded by saying that in all cases of wounds of the throat tracheotomy should not be lost sight of.

Fracture of Os Frontis.—On the 30th of January, 1850, Mr. Moxhay presented an interesting specimen of fracture of the *os frontis* extending into the orbit, in a butcher's boy, who was caught on a hook, which punctured the roof of the orbit and so entered the skull, but the brain was not wounded. The accident occurred thus:—The boy was in the act of jumping off one of the benches in his master's shop, when he sprang his forehead against one of the bars, and in falling was caught by one of the hooks which was attached to the bar.

Mr. Moxhay also presented another case of fractured skull, extending into the orbit, caused by the kick of a horse.

Bifurcation of the Fifth Rib.—On the 29th of May, Mr. Jeston, jun., presented as a curious malformation, the fifth rib of the left side of a man, which spread out at its anterior extremity to nearly double its natural breadth, and, bifurcating, became united with two cartilages, which joined each other before reaching the sternum.

Cases in Obstetrics.

On the 27th of March Mr. Vines read a paper on some cases in obstetrics. For this most able and useful paper Mr. Vines received the thanks of the Society. The cases are, most of them, of great practical importance, but I regret that my limits will allow me only to notice the salient points of each.

Case 1.—Mrs. T. suffered from profuse hæmorrhage for three days previous to labour. The second stage of labour having set in, and the midwife finding no progress was made in the descent of the head, and the hæmorrhage continuing, Mr. Vines was sent for. On arrival he found the os uteri fully dilated, but the head of the child quite at the brim of the pelvis, resting on the brim. He directed the patient to lie on her back, and gave ergot. The position of the child was soon changed, the descent of the head took place, and the child was born in the course of an hour or two. The after hæmorrhage was not excessive. The placenta was double, and covered a large surface of the uterus. The uterine contractions, which were rendered spasmodic and irregular, through the head of the child lodging on the pubes, caused a portion of the placenta to be detached, and thus gave rise to the hæmorrhage. The patient did well.

Case 2.—An exceedingly stout woman, the mother of twelve children, was attended by a midwife. Seven hours after the birth of the child Mr. Vines was sent for. He found the placenta retained, and profuse hæmorrhage going on, the woman being reduced to a state of great exhaustion. On examination there was found a cartilaginous attachment of the placenta, and great difficulty was experienced in effecting its separation; this being done a dose of ergot, with brandy, was given, but the uterus being very slow in contracting, one hand was placed within the womb, while the other grasped the parietes of the abdomen, and made firm pressure on the uterus, the hand being occasionally dipped in cold water, thus contraction was at length ensured. The patient was afterwards tightly bandaged, and the ergot and tincture of opium repeated in small doses.

Case 3.—Mrs. H., between six and seven months advanced in pregnancy, had suffered from slight internal hæmorrhage for the last two months. On examination a partial presentation of the placenta was discovered. Two or three doses of ergot were given, at intervals of two hours, and when labour pains had set in, the membranes were punctured with a female catheter. The delivery was speedily effected, and the patient did well.

The same woman again came under Mr. Vines for placenta prævia. During the ten days previous to delivery hæmorrhage went on, and at length the symptoms becoming serious, it was thought advisable to effect delivery, which was accomplished by turning, ergot being first exhibited.

Case 5.—Mary H., a short, hump-backed, exceedingly deformed person, whose complaints were at first attributed to anything but labour-pains. On examination the os uteri had fully dilated, but the child's head was quite at the brim. The conjugate diameter scarcely measured more than two inches and a half. The child's head was perforated, and after considerable exertion delivery was effected. The patient bore the operation well, and soon recovered.

Case 6.—Had been in labour three days, attended by a midwife. Mr. Vines found the head impacted in the upper part of the pelvis. The forceps were introduced but could not be passed over the child's head. The patient's strength was failing and the uterine pains had almost ceased; from the fœtid smell of the discharge there could be no doubt the fœtus was dead. Some ergot with a little brandy was given, and the head perforated. Delivery soon terminated. For some days subsequently the urine passed away owing to paralysis of the bladder, from the long-continued pressure of the child's head. Small doses of copaiba and turpentine were given and the patient ultimately did well. She has since borne two or three children.

Case 7.—Was a foot presentation, having been twenty-four hours in labour, attended by a midwife. Mr. Vines, when sent for, found both knees resting on the pubic bones. Traction of the legs was exerted backwards and then downwards, and the knees being dislodged the child was drawn easily through the pelvis. The child was still-born.

Case 8.—A very similar case, but here both feet presented; the knees were found to lodge on the pubes

with the child's head between them. A good deal of hæmorrhage was going on. By putting a hand upon the abdomen, just above the pubes, the child was without much difficulty pulled from its position and delivery shortly accomplished.

Case 9.—Had been in labour twenty-four hours. The os was found dilated and the pains strong but of no avail; the head was firmly fixed at the brim of the pelvis. The forceps were tried without avail, and delivery was effected by craniotomy. This woman had given birth to four living girls, but all the male children, six in number, had either died or been destroyed in their birth. Fifteen or sixteen months afterwards this woman became again pregnant. The idea of inducing labour at the seventh month was thought of, but abandoned. As before, the expulsive pains were of no avail, but by an earlier application of the forceps Mr. Vines hoped he might be successful, and with great difficulty he at last brought a living male child into the world—not, however, without two or three slight injuries from which he speedily recovered. On removing the placenta a fibrous tumour with a long pedicle came away with it, and probably, Mr. Vines thought, a tumour of this description, by passing down between the cranial and pelvic bones, might have been one cause of her difficult labours.

Case 11.—Was a lingering and painful labour, owing to a disproportion between the size of the child's head and the pelvis. Mr. Vines finding at length that no progress was made, the mother's strength failing, and fearing convulsions, used the *blunt hook* for the purpose of drawing down the head; at length the child was born, and *alive*, much to Mr. Vine's astonishment; he had contemplated that the child was dead or he would not have used the hook so freely. The child sustained some injuries by its use, but recovered; and ever since then, now five years ago, Mr. Vines has felt a reluctance to use the instrument.

Case 12.—A first labour was peculiar from the length of the umbilical cord, it being thirty-nine inches long.

Case 13.—Was peculiar from the cord being twisted *five* times round the child's neck: it was also a case of *post-partum* hœmorrhage.

Case 14.—Another case, in which although the woman had had three living female children, a male child could not be born, and craniotomy was obliged to be performed. This was the second time it had been resorted to.

Case 15.—Had been three days in labour when the midwife requested Mr. Vines should be sent for. He found the head lodged at the brim of the pelvis and a face presentation; the midwife had mistaken the child's cheek for a tumour of the vagina: the patient was in a very exhausted state. By fixing the blunt hook under the child's chin and using considerable traction, delivery was accomplished; the child was still born; the mother did well. About two years afterwards, this woman requested Mr. Vines to attend her again; this was her eighth pregnancy, and she had never given birth to a *full-grown* living child. Twice she had had labours induced at the seventh month, and these two children were still living. Mr. Vines also intended to have brought on labour on the seventh month, but was prevented through illness, and at the full time, after waiting many hours, tried to deliver by the forceps, but failing, at length resorted to craniotomy. The woman did well. The obstacle to delivery was caused by the projection of the promontory of the sacrum.

Case 17.—Was a face presentation, in which the child's mouth could be felt through the membranes opening and shutting, and on pushing the finger into the mouth the action of *sucking* was distinctly recognised.

Case 18.—Was a very rapid labour, and on Mr. Vine's arrival the child was found in the bed enveloped in its membranes and floating in the liquor amnii; he was obliged to open the amnion with a pair of scissors to let out the child which was still-born.

Case 19.—Aged 30. A most tedious first labour; the parts being very rigid; the placenta with great difficulty extracted, from hour-glass contraction of the womb. The spasm of the vagina, as well as uterus, was excessive. Hot napkins, friction, and pressure were used, and an opiate given. Considerable hæmorrhage followed, but the case ultimately did well.

Case 20.—A woman of small stature, with contracted pelvis. Had had two still-born children at intervals of two and three years. Mr. Vines brought on labour at the seventh month. When the os uteri had well dilated there was no disposition for the child's head to descend below the brim; it was therefore found necessary to turn. So narrow was the pelvis that the hand could scarcely be passed; and the difficulty of the case was increased by the placenta having become detached, and moving about from side to side in the uterus, and coming in the way whenever it was attempted to lay hold of the feet. After many fruitless efforts the delivery was effected, and the mother did well. The child had been dead many hours.

Mr. Vines observed, in reviewing the preceding cases, that his attention had been particularly directed to one point, viz., the preponderance in size of the male fœtal head over the female; and, in consequence, the frequent occurrence of those cases in which, although the mother can readily give birth to living female children, the males are all born dead.

Cholera.

There is one other subject, gentlemen, which has occupied some share of your attention during the past year, viz., cholera. Fortunately, however, amid the devastation by which we have on all sides been surrounded, this town and neighbourhood have been nearly, if not altogether, exempt from its ravages; and grateful should we be to that Providence which among the general visitation has so lightly passed over us. As this subject,

also, was treated of rather largely in the last year's Address, and as among the few cases which have been reported I can find none which throw any fresh light either upon the pathology or treatment of the disease, I have not thought it worth while further to add to the length of this report, or to the already overwhelming mass of crude materials accumulated of late in our periodical literature, by entering upon this subject now.

I have now only to renew our expressions of obligation to Dr. Woodhouse and Mr. Harrinson for their continued and unwearied exertions as secretaries; and for the first time to express our thanks to our curator, Mr. Moxhay, for his labours in adorning this museum; and I am confident that to no one more than himself would an increase of those labours give greater satisfaction.

In conclusion, Mr. President and gentlemen, while I cannot but be conscious of the many defects of this Retrospective Address, I yet hope it has not altogether failed in its object of being a faithful though concise account of your proceedings. My aim has been to be an historian rather than a critic; for which latter office, indeed, neither my attainments nor my age have fitted me. I beg to thank you for your kindness and attention.

BATH AND BRISTOL BRANCH.

The quarterly meeting of the Bath and Bristol Branch of the Association was held at the York House, Bath, on December 19th, 1850; Dr. Hodges in the chair.

There were present—Drs. Burne, Boyd, Davies, Falconer, Gidler, Goodridge, Tunstall, and Jas. Watson, Messrs. J. Barrett, Bartrum, Boult, Brace, Cox, Evans, R. Godfrey, Hensley, Hunt, King, Kilvert, Mitchell, Norman, Ronald, J. S. Soden, J. Soden, Stockwell, Stone, Skinner, Skeate, and Terry, of Bath; Dr. Swayne, Messrs. Colthurst, Godfrey, Mayor, Morgan, Nield, Wilson, and — Wilson, of Bristol; Dr. Morgan, of Turley; Messrs. Washbourne, of Corsham; Flower, of Chilcompton; Collins, of Chew Magna, Ogilvie, of Stapleton; Crouch, of Bruton; and Edwards, of Batheaston, &c.

The minutes of the last meeting were read and confirmed.

Mr. Wilson read the history of four cases of ovarian dropsy that had been operated on, one by the application of caustic potass and the formation of an oviduct; the other three had the ovarian sac removed, two of them successfully. (This paper will be found published at page 33 of this *Journal.)*

Mr. Norman then gave the history of a case in which the abdominal cavity had been opened for the removal of a tumour of the ovarium, which was too adherent to be removed; the case not ending fatally. He then gave the history of several other cases, where the disease had spontaneously subsided. (Published at page 5 of this *Journal.*)

Mr. Stockwell detailed the symptoms and *post-mortem* appearances of a case of ovariotomy that ended fatally on the fourth day after the operation. (Published at page 37 of this *Journal.)*

Mr. Crouch would not advocate the performance of ovariotomy in any case, unless the operation and its probable success were fairly open to the examination of the profession. At the meeting of the Medico-Chirurgical Society of London it was observed that the operation was wholly unjustifiable, one case only out of ten having succeeded in the hands of the hospital surgeons of London; which probably might be explained by the bad air of London. At that meeting one gentleman was reported to have said that no case of this disease would justify surgical interference. If, however, we compared the results of this with other capital operations, they would not be found more unfavourable than in them. For example, of one hundred and thirty operated on in Great Britain thirty-eight had terminated fatally; which, if compared with the mortality of amputation, would not be found more unfavourable. At the meetings of this Branch there had been reported, within a limited period, seven operations; of these, two had been fatal, one unsuccessful, and four had recovered. Of the one hundred and thirty cases reported, at least fifty lives had been saved; for these reasons he could not consider the operation unjustifiable. In disease of the arteria innominata ten cases had been operated on, all of which had ended fatally. This did not, however, preclude the hope of some case at a future time having a more favourable issue, from an operation on the distal side. As the symptoms and diagnosis of ovarian disease became more perfect it was to be expected that the operation, in suitable cases, would be followed by a large proportion of recoveries.

Mr. J. Barrett could not consider this line of argument tenable, for in disease of the arteria innominata death was quite certain, whereas in ovarian disease death was not nearly so certain, nor was life so quickly cut off; for of the hundred and thirty cases mentioned, probably not half would have died of it immediately. On these grounds he could not consider Mr. Crouch's reasoning quite applicable.

Mr. Norman agreed with Mr. Barrett that this argument was not applicable. On one occasion, in 1824, he had tied the arteria innominata, though he was bound to confess he did not intend to do so, when commencing the operation. He purposed tying the artery internal to the scaleni, but finding it there diseased he proceeded to apply the ligature to the innominata, which was successfully accomplished; still this would not induce him again to undertake it.*

Dr. Burne observed that every thing depended on the accurate diagnosis of the peculiar nature of the disease; if the medical attendant had noticed in the progress of the case, or from its history had reason to suspect, any inflammatory disease of the sac, he, of course, would not be justified in attempting it. Dr.

* This man lived six days after the operation, and died probably from pericarditis, the whole of that membrane being covered with a lace-work of recent lymph. The preparation is in the Museum of the Bath United Hospital; the ligature remains on the arteria innominata; there is a perfectly formed clot on the side next to the heart as well as on the outer side of the ligature, and a clot extends nearly the whole length of the common carotid.

Bright had drawn the attention of the profession to the peculiar crepitation often well marked in circumscribed peritonitis, which symptom, when present, was of great diagnostic value; the post-mortem examination of cases characterised by this crepitus having revealed the existence of adhesions dependent on the effusion of lymph. Of course, when the tumour has been formed, this symptom will no longer avail. In his work "On Operative Surgery," Mr. Skey had observed that, often from careful examination of the tumour you form a pretty accurate diagnosis whether the fluid was limpid or gelatinous, and that in proportion as the fluid was limpid or no, so was it favourable for an operation or the reverse. The instrument exhibited by Mr. Wilson resembled in principle that used for the spaying of animals.

Mr. Wilson did not wish to claim for himself the originating the idea of the tourniquet just exhibited for confining the sac, Ricord's instrument for phymosis having suggested it; this latter had the disadvantage of requiring an assistant to hold it, which his did not. On a smaller scale he first used it for removing very enlarged nymphæ. In all these cases the point of importance was the diagnosis, as there were cases of fibrous tumours of the ovary, which, like the fibrous tumour of the uterus might take on a malignant form. His operation was only applicable to those with fluid contents. If the fluid was dark, contained blood discs and cholesterine, he augured unfavourably; if, on the contrary, the fluid was limped and straw-coloured, and the sac could be emptied without leaving any solid substance, the case promised well. He could not concur with Mr. Crouch in his comparison of disease of the arteria innominata, though the fullest tables of disease of the ovary showed that it lessened the duration of life much more than was commonly supposed. It had been laid down that four or five years was about the average duration of life of those afflicted with this disease; he could, however, scarcely suppose that it was so much shortened; it might be so on the whole, but a distinction must be made between those of an acute character, leading rapidly to a fatal termination, and those of a more chronic nature, occurring often at a later period of life, which might exist for a long time without requiring any operative treatment; still cases would occasionally occur that imperatively called for surgical interference. In the fatal case he had just recorded he believed that the ligature around the pedicle (which after the operation contracted considerably) was the cause of the fatal issue, having led to the inflammation of the uterine peritoneum. Had he, now, to decide upon these cases laid before the meeting he should feel quite justified in repeating the operation, after stating distinctly to the patient the risks she incurred, leaving her to decide whether she would undergo them. After his experience in this disease, he would rather remove the ovary than form an oviduct, his patient having for some time been in the most imminent peril.

Mr. Bartrum having been present at the operations on the fatal cases narrated, thought that, but for the unfortunate slipping of the ligature in Mr. Wilson's last case, it promised as successful a termination as his previous two, both of whom he had seen perfectly recovered. From the large ligature slipping a considerable quantity of blood was effused, which he thought had much to do with the unfavourable issue, though, as in Mr. Stockwell's case, the ligature on the pedicle appeared to be the immediate source of inflammatory action. There was also a great difference in the contents of the two sacs; in the one it was limpid as water, in the other it resembled thin pus, of a greenish yellow hue. If the ligature in either case could have been retained as far from the uterus as it appeared to be during life, probably inflammation would not have arisen; for in neither case was there but the slightest traction used. Mr. Wilson's operation, just laid before the meeting, avoids that great source of danger, and affords, in cases where it is applicable, the probability of a more favourable result than any that has yet been suggested. Still there will be great difficulty in distinguishing between the unilocular and multilocular sac; and further experience is needed to see whether the ova that are left behind may not after a time enlarge, come forward, and require further surgical interference. The multilocular sacs will probably be found unfavourable for the operation, as they are often tied down by numerous adhesions.

Mr. Norman thought that the two fatal cases just narrated went far to prove that a ligature placed too near the uterus is likely to be injurious. The cases of the usual ovarian dropsy, such as those of Mr. Wilson, filled with limpid or pale serum, were likely to be cured by the operation now laid before the meeting—by puncturing and emptying the sac, and cutting off a portion of it, putting ligatures on the arteries. Forty years ago he had seen this done. The surgeon made an incision and passed in the trocar; the cannula having accidentally slipped the sac protruded at the wound, and could not be returned; he then cut off a portion of the protruding membrane. The patient recovered permanently, and never again required tapping.

Mr. Hunt then exhibited a beautiful specimen of a very rare disease of the gastric mucous membrane, and gave the following history of the case:—

A gentleman, aged 67, has been known to Mr. Hunt for the last twelve years, during which period he had several attacks of inflammation of the pharynx and soft palate, which presented a character resembling erysipelas. There was some slight difficulty of swallowing, distressing eructations, and heartburn. Under treatment these always subsided. Two months previous to his decease the symptoms assumed a different aspect: the breathing difficult, countenance blue, and feeble pulse, with other symptoms, indicating that the heart was the organ more immediately affected; he complained likewise of distressing weakness and a constant desire for food; and after making some exertion to get up stairs to his bed-room he died suddenly.

Post-mortem.—Lungs healthy. Heart flabby, the walls of the left auricle so attenuated and dilated that on holding it up to the light they appeared more like a diaphonous membrane; the left auriculo-ventricular opening was so patent that it admitted of regurgitation, thus accounting for the sudden death. Liver healthy. On opening the stomach an appearance rather unexpected was observed, as may be seen in the specimen laid before the Association. Along the course of the

larger curvature of the stomach the mucous glands are so enlarged as to present the appearances of clusters, three generally in each cluster. The mucous membrane was thickened and vascular. The best—in fact the only description of this disease known to Mr. Hunt may be be found in "Rokitansky's Pathological Anatomy," (Sydenham Society,) page 25, where, after describing the kinds of inflammation of the mucous membrane of the stomach, he says:—"In a higher degree it presents, in addition to its increased thickness, an uneven, racemose, or warty surface—a *surface mamellonée*. In a still more advanced degree it forms prolongations, in the shape of permanent firm folds, or of polypus." The specimen shown may be said to combine these two degrees.

It should be said that during the period this gentleman has been known to me his habits have been most abstemious, and he never complained of any pain of the stomach.

Foreign Department.

Anæsthesia in Midwifery.—By Dr. Aran.

[Dr. Aran has undertaken a report on the "Induction of Anæsthesia in Surgery and Midwifery," part of which was published in the *Archives Générales* of last March. The concluding portion, which refers to the use of chloroform in midwifery, we now translate in an abbreviated form. Dr. Aran proceeds as follows:—]

In entering upon this portion of my labours, I cannot avoid expressing my regret that so little aid is afforded me by the writings of French authors. It is true that M. Paul Dubois was not slow in repeating the experiments of Dr. Simpson, and in acquiescing in the views of the learned Edinburgh Professor; but here, as far as our country is concerned, the scientific history of anæsthetic agents ends, while in England numerous publications testify the interest with which the use of anæsthesia in obstetrics is regarded. Doubtless our countrymen have been scared by the cases of death which have from time to time followed the use of chloroform in surgery, but they should be made aware, that although it has been used in labour in innumerable cases, not a single instance has occurred to induce apprehension as to the effects of that agent upon the lying-in women. Whether this immunity from danger depends, as is thought by Dr. Beatty, upon the circumstance of the horizontal position being maintained during inhalation, or upon the state of emptiness of the stomach, or upon the fact that the anæsthetic effects are not needed to be carried to so great an extent in midwifery as in surgical operations, certain it is that the fact of comparative innocuity of anæsthesia in obstetrics has been ascertained in England, and should have due weight with us.

In order to form a correct estimate of the state of the question, the author thinks it necessary to recapitulate the conclusions of Dr. Simpson's first and second memoirs, in which it is stated that consciousness may be abolished without diminishing the force or frequency of the uterine contractions. This done he proceeds to inquire into the results of later experience; and, firstly, he demands—

"*What is the action of anæsthetic agents on the uterus and abdominal muscles?* 'Contractions' and 'pains' have been used synonymously in obstetrical language, giving rise to a confusion which has in itself had no slight effect in deterring practitioners from using anæsthetic agents. They feared that to annul *pain* was to destroy uterine *contraction*. Etherization, however, has established the physiological independence of uterine action and physical suffering, and has proved, satisfactorily, that it is possible for all consciousness to be abolished and the uterine action thus to be artificially made to enter into the class of the organic functions of life, of which the sensorium takes no cognizance.

As regards the exact condition of the uterine contractions during the anæsthetic state, very contradictory opinions have been recorded. Simpson and Dubois affirm that the contractions are normal, and the same opinion is maintained by Dr. Murphy, who informs us that chloroform does not diminish the action either of the uterus or the abdominal muscles, unless it be carried to an unnecessary extent. The same evidence in substance is also afforded by Dr. Prothero Smith, Mr. Snow, and Mr. Denham. There can, therefore, be no doubt that the contractions are modified by inhalation, and that they may be weakened or altogether suspended; but it is equally certain that these effects will not occur in ordinary cases, unless either the inhalation has been carried to an unnecessary depth, or the individual is peculiarly susceptible.

Does the perineum become relaxed during anæsthesia? This question also has been differently answered by accoucheurs. It is affirmative in the case of MM. Dubois, Protheroe Smith, Merriman and Beaumont; it is on the other hand denied by Mr. Denham.

En resumé it may be said in reference to the action of anæsthetic agents on the contractility of the uterus and abdominal muscles, that it is possible to obtain a complete anæsthetic effect without paralyzing the uterus; that the intervals between the pains may be lengthened, and the contractions momentarily suppressed, without any real failure of the contractile power of the organ; and that when the inhalation in such cases is suspended, the contractions return with augmented force, and this even before the woman has entirely regained her consciousness.

[M. Aran, next inquires into the effect of chloroform on the health of mother and child. This portion of his essay we must postpone to our next number.]

Cretinism.

A recent communication on this subject by M. Boudin, founded on the report of the Sardinian Commissioners, is published in the *Archives Générales*, September, 1850. This commission defines cretinism to be "a degeneration of the human species, which manifests itself in different parts of the globe, and characterised by idiocy, more or less pronounced,

associated with malformation of the body." It has been observed in Europe in the Alps, the Pyrenees, the Jura, the Hartz, and the Carpathians; in America, in the Cordileras; in Asia, in the Himalayas, and in the mountainous districts of Tartary.

Sometimes the affection appears at birth, but generally no sign of the cretin appears till subsequently. The stature is seldom over four feet, many do not surpass three feet six. They are generally thin, with tawny skin, and a countenance expressive of a brutal deficiency of intelligence. The head is misshapen and out of proportion; the muscular strength is below par; the articulation imperfect. The cretin has few diseases, pellagra is, however, not infreqnent in the valley of the Po.

As far as the commission could gain information, season had no influence on the propagation of cretins. Other statistical facts, of more or less interest, are as follow:—

Cretinism declared itself—

Between birth and the age of	2	years	in		4,440
,,	2	,,	5	,,	187
,,	5	,,	12	,,	202
,,	12	,,	20	,,	31
Above	20	,,	—	,,	28

In goitrous cretins, the goitre commenced—

Between birth and the age of	2	years	in		2,333
,,	2	,,	5	,,	199
,,	5	,,	12	,,	419
,,	12	,,	20	,,	31
Above	20	,,	—	,,	28
Age not specified		,,	—	,,	711
					3,912

In analyzing these and other tables, the commission have ascertained that hereditary influence is not powerful in the production of cretinism, as out of 8,000 families of cretins, not more than 300 parents were the subjects of the malady.

In reference to the locality, the commission have established that deep, narrow, and tortuous valleys, abound the most with cretins, and that the villages in which they reside are remarkable for the abundance of stagnant water. They have also made out that the water is highly charged with lime and deficient in iodine and bromine.

The commission have determined that the eradication of cretinism is best effected by the following hygienic precautions:—To drain the valleys; to cut down unnecesary trees, so as to allow of a free circulation of air; to furnish a purer water; to insist upon houses being built on sanitary principles. To encourage a meat diet, and the liberal use of salt; to prevent, as far as possible, the marriages of cretins, scrofulous and ricketty persons.

General Retrospect.

PRACTICAL MEDICINE.

Ossification of the Pericardium.—By Mr. Canton.

At a recent meeting of the London Pathological Society a specimen of this interesting lesion was exhibited. The patient was a boy aged eleven, who, in 1844, was the subject of rheumatism, complicated with pericarditis, and was treated in the usual manner. The results were the persistence of turbulent action of the heart, with dyspnœa; in all other respects he enjoyed tolerable health until Nov., 1845, when pain in the region of the heart required antiphlogistic treatment, and blistering for a short time. In April, 1846, he became the subject of a severe attack of hæmoptysis, which being subdued was followed by ascites—this latter was with difficulty removed by diuretics in June. In June, 1847, ascites reappeared, but was again removed by the same plan of treatment. In Sept., 1848, he was again dropsical, and continued so for several weeks. The ascites occurred at the close of 1849, accompanied by a severe attack of hœmoptysis, which for several days threatened his existence, but was ultimately stayed by gallic acid. His sufferings during the last three years had been very severe, and from this date (Nov. 1849) were still augmented, and obliged him to pass several successive nights supported in a chair. There was great abdominal distension, attended at times with severe pain in the epigastric region, œdema of the lower extremities and of the scrotum: a more formidable attack of hæmoptysis again took piace in July, and lasted ten days. It now became manifest that the long-continued sufferings of the patient were drawing to a close; the dyspnœa became painfully urgent; the ascites was no longer amenable to treatment, and the violent action of the heart prevented his sleeping. Repeated auscultation led to the conclusion that extensive adhesion of the pericardium was present, with hypertrophy of the heart; some disease of the valves was suspected. During the whole of his illness the pulse maintained a strong, full, and rapid beat, and lessened the suspicions of valvular disease. The carotid and temporal arteries pulsated violently; a dry cough repeatedly harassed him, especially towards the close of his existence. Notwithstanding his disease and suffering he grew in stature. He died suddenly.

After death the anterior mediastinum was found filled with lymph; the pericardium was firmly adherent to the heart; and bone was deposited in a ring an inch wide, encircling the organ between the auricles and ventricles. The heart was enlarged and thickened.—*Lancet*, Nov. 30.

SURGERY.

Bubo, with Perforation of the Abdomen, and Peritonitis.—By Dr. Lente.

A mechanic, aged 22, had a suppurating bubo in the groin, which had opened spontaneously. The patient

had in this state continued his work, which required a violent strain upon the abdominal muscles. He was placed on low diet and poulticed, the undermined edges of the bubo being pared off with scissors. The patient did well for a week, when about ten P.M., of June 8th, after vomiting, he was found in a state of great prostration, with sunken countenance, cold skin, small rapid pulse; *no pain on pressure* on the abdomen. After a period of eighteen hours this symptom, however, appeared, and the vomiting became unmanageable. Leeches were applied to the epigastrium, and calomel and opium exhibited without benefit, and the patient died at seven A.M. of the 10th.

Autopsy, sixteen hours after death.—An examination was only allowed of the abdomen. Before making an incision, examined the bubo with a probe, which passed into the cavity of the abdomen its whole length without difficulty. Upon laying open the latter, a quantity of serum, rendered turbid by lymph, gushed out, and the intestines throughout were seen to be glued together by recent exudation of lymph, and the vessels of the peritoneum generally injected. Upon tracing the intestine along towards the bubo, found the large bowel, just before it gives place to the sigmoid flexure, firmly glued to the internal wall of the abdomen, at a point corresponding to the situation of the bubo, by fibrinous bands, to the extent of an inch or more; these were evidently the product of recent inflammation, but admitted of considerable traction without giving way; the intestine was now slit open, and the ulceration found not to have communicated with it. The opening into the peritoneal cavity was found to be near the left sacro-iliac synchondrosis, close to the bifurcation of the common iliac artery, and was one-third of an inch in diameter, being of a circular form; pus was seen oozing from it into the peritoneal cavity. Other abdominal organs, except those mentioned, were found to be healthy.

The author remarks that this is probably the only case of perforation of the abdomen by a bubo on record; and that this fact prevented a suspicion of the actual state of the case until after death, and also an *ante-mortem* examination with the probe, which would have revealed the origin of the obstinate symptoms above enumerated. An attempt was made by nature in this case, such as she often makes in similar difficulties, to avert a fatal issue by causing the opening to take place into the cavity of the large intestine instead of into that of the peritoneum; for this purpose the former was glued to the latter at the point where the communication should have taken place; but unfortunately, the matter took a longer course, and opened beyond the adhesion.—*New York Journal of Medicine*, Sept., 1850.

Wound of the Stomach: Recovery.—By Dr. Forsyth.

The author was called to a police constable who had stabbed himself intentionally with a bayonet. He was found standing in the middle of the room, with staring eyes, and trembling of his entire frame. A little to the left of the centre of the scrobiculus cordis there appeared the mark of a bayonet wound. He said he had pierced himself with his bayonet to the depth of four inches and a half. The weapon being examined, showed that it had been introduced fully to that extent. There was no external hæmorrhage worth mentioning, but he repeatedly declared that he felt the blood flowing down internally, and that he was sure he would not live an hour. The author had him stripped, and laid down in bed. He called incessantly for drink. In the space of an hour he got four or five seidlitz draughts, which he drank with the greatest greediness. Through the night he took ten such draughts, besides amazing quantities of cold water, strongly acidulated with sulphuric acid. He again and again declared that he was dying, and expressed the greatest anxiety to see a priest. One was obtained from Belfast.

Wednesday morning, at four o'clock, he was tranquil, with a pulse which had fluctuated exceedingly in the first part of the night, soft, steady, and beating only 70 in a minute. He had vomited much, and his bowels had been greatly acted upon. The evacuations were thin and bloody, leaving no doubt that the bayonet had pierced the stomach, from which the blood flowed. The most perfect rest, quiet, and total abstinence from food, were recommended through the whole of this day and ensuing night, and on Thursday morning he said he felt astonishingly well. His thirst had greatly abated; pulse only 65; pain of wound not severe. He got for breakfast a cup of tea, about blood heat, without bread, and in the evening he had a little arrowroot. His bowels continued free.

Friday morning he said that he was without pain of any kind, and took for breakfast a cup of arrowroot. A similar quantity he took again in the evening. Saturday morning he said that he had rested well through the night, and felt no pain. His bowels were sufficiently open.

Being assured, on Sunday morning, that nothing was the matter with him, and the wound appearing to be completely closed, he was allowed to walk through his room, and all medicines were omitted.—*Medical Times*, November 9, 1850.

MIDWIFERY.

Puerperal Fever and Surgical Fever—their Analogies.—By Dr. Simpson.

In an essay published in the *Edinburgh Monthly Journal*, Dr. Simpson states the analogies of puerperal and traumatic fever, under four points of view:—1. In the anatomical condition, and constitutional peculiarities of the subjects of these fevers. 2. In the pathological nature of the fever. 3. In the morbid lesions found after death. 4. In the symptoms which accompany each affection.

He shows, in the first place, that the anatomical conditions of the puerperal patients, and the subject of an operation, are in many respects the same. Both have an open wound, with exposed vascular orifices;—both are liable at the first to present symptoms of shock or collapse;—both have generally a limited febrile reaction—the traumatic fever in the one case, the milk

fever in the other. Both the external surgical, and the internal obstetrical, wounds are liable to deviate from the standard mode of separation; and may have altered secretions, excessive inflammation, or phlebitic suppuration. In both air may enter the veins, both may give rise to delirium, tetanus, and other nervous complications.

In pointing out the analogies of puerperal and surgical fever in their essence, Dr. Simpson reviews the various opinions of the nature of puerperal fever which have prevailed from time to time, stating his own to be in accordance with that generally received, viz., that it is due to a vitiation of the blood, which he also shows to be the cause of the fever which too often follows severe operations. Both in their phenomena and results correspond with other "disseminated inflammations," as they are termed by Chomel, such as scarlatina, erysipelas, &c.

He next follows the analogies of the two diseases, by exhibiting a tabular record of their marked appearances, from which it is seen that both leave traces of acute internal inflammation, which are seldom limited to one organ or texture, but are distributed over several simultaneously. It is also observed, that the internal viscera, which are the principal seats of the inflammation, are often distant from the original wound or lesion. The great resemblance which exists in the symptoms is next pointed out, and the author concludes his essay with some remarks on the contagious nature of these fevers, and on the precautions which should be taken to prevent or limit their outbreak.—*Edinburgh Monthly Journal*, November, 1850.

Cæsarean Operation.—By Mr. Sanneman.

The patient in this case was a woman aged 42, of small stature, and old appearance. She had produced six children, the last requiring craniotomy, seven years since. In consequence of an accident to the spine eleven years previously, symptoms of malacostem ensued, which had gradually distorted her figure. Her health was much deteriorated, and the urine deposited phosphates.

When visited (Jan. 11, 1848), in addition to the symptoms mentioned above, she had had several slight epileptic convulsions, and had been suffering severely from chronic bronchitis; she was at this time in the seventh month of pregnancy. On examination *per vaginam*, the pelvis was found greatly deformed, the acetabula being pushed backwards and inwards towards the sacrum, and the ossa pubis forming a projecting angle at the symphysis. In consequence of this deformity, the uterus was anteverted to the greatest possible degree.

Mr. Sanneman was called to her at two o'clock A.M., Feb. 28, and found that moderate labour-pains had commenced; the uterine tumour formed a large pendulous body projecting over the symphysis pubis, and its lower border occupying the space between the thighs; it could be elevated or moved to either side with ease. The abdominal parietes were so much attenuated that the child felt to the hand as if extra-uterine. On examination *per vaginam*, the tip of the finger could just reach a soft spongy mass, which appeared to be placenta, and there was considerable hæmorrhage during the pains. The antero-posterior diameter of the pelvis appeared to be about two inches; but from the displacement of the acetabula, the capacity of the pelvis generally, and the dimensions of the other diameters, were so dimished as to preclude the possibility of delivery by other means than the Cæsarean section, which, after a consultation with Messrs. Bennett and Barratt, was accordingly performed twelve hours after the accession of pains.

The first incision, five inches in length, was made over the most projecting part of the tumour, considerably to the right of the mesian line, and from the excessive attenuation of their abdominal walls, it at once exposed the uterus. The next incision divided the uterine parietes; the child and secundines (the latter presenting at the os uteri with the shoulder of the child) were immediately extracted. The uterus contracted rapidly and firmly; the edges of the wound were brought together by interrupted sutures and adhesive strapping, and a bandage applied. The child was dead. The operation did not occupy more than two minutes, and not two ounces of blood were lost. The patient bore the proceeding with the greatest fortitude. For twelve hours afterwards she had not a bad symptom. Full doses of opium were administered. She was, however, seized with a severe epileptic attack, and this was twice repeated before death, which occurred, apparently from exhaustion, at two o'clock on the day following. She thus survived the operation 23 hours.

Autopsy, March 1, 1848.—The uterus was found firmly contracted, of the size of a cricket-ball, and containing a coagulum. The part where the incision was made was in contact with the rectum. On measurement we found the diameters of the pelvis as follows:—The antero-posterior scarcely two inches, the transverse three inches, the acetabula projecting upwards and inwards to the sacrum, thereby lessening very considerably the oblique diameter. The other viscera appeared pretty healthy.

When the labour set in, Mr. Sanneman was in hope that craniotomy might be attempted, and if found impracticable, as a last resource, he determined to perform the Cæsarean section; but when the placenta was found presenting, and the hæmorrhage urgent, he decided that the nature of the pelvic distortion, and the anomalous situation of the uterus, left him no option.—*Lancet.*

A BILL

FOR THE INCORPORATION OF GENERAL PRACTITIONERS IN MEDICINE, SURGERY, AND MIDWIFERY.*

[Note.—The words printed in *Italics* are proposed to be inserted in the Committee.

XIII. And be it enacted, that the Council of the said College shall consist of forty-eight of the members

* Concluded from our last number.

of the said College, of whom not less than twenty-four shall reside within ten miles, by highway or road, from the General Post Office in the city of London.

XIV. And be it enacted, that the before-mentioned shall be the first President of the said College, and shall continue as such President until the last Wednesday in the month of *one thousand eight hundred and* and thenceforth until his successor shall be elected as hereinafter provided, and he shall then go out of office; and on the last Wednesday in the month of *in the year one thousand eight hundred and* and on the last Wednesday in the month of in every third succeeding year, the Council of the College shall meet in the Common Hall for the time being of the said College, or in such other place as the said Council shall from time to time direct, and shall elect a President from those members who are qualified to be elected President as hereinafter provided; and every President so elected shall continue to be President for *three* years, and until his successor shall be appointed, and shall then go out of office; and the President for the time being shall always be considered as a component part of the Council.

XV. And be it enacted, That shall be the first members of the said Council resident within such ten miles as aforesaid, and shall be the first other members of the said Council, and such members shall all continue of the Council until the several days and times herein-after mentioned, and until the successors of those who shall then be the members to go out of office shall be elected; and on the last Wednesday in the month of in each of the years *one thousand eight hundred and* *and one thousand eight hnndred and* *one third* of the members resident within such *ten* miles as aforesaid, and one third of the other members or the said Council hereinbefore named, shall go out of office, in the order in which the Council shall in each of such years appoint among themselves, and shall not be re-eligible on the Council until the year following that in which they shall go out of office.

XVI. And be it enacted, That the Council shall be hereafter elected by a majority of the votes of such members of the College for the time being as at the time of such election shall either have been for *five* years members of the said College or shall have possessed the diploma or licence by virtue of which they shall be members of the said College for at least five years before the day of election, and such members shall be entitled to give their votes either personally, or by proxy in writing, according to such regulations as the Council shall establish by any bye-law; and on the last Wednesday in the month of *in the year one thousand eight hundred and* and on the last Wednesday in the month of in every following year, such of the members of the College as shall for the time being be entitled to vote as aforesaid shall meet in the Common Hall for the time being of the said College, or in such other place as aforesaid, and shall elect, from those members who shall be qualified to be elected as hereafter provided, eight persons resident within ten miles as aforesaid, and eight other persons, to be members of the said Council, and every such member so elected shall continue of the Council for three years, and until his successor shall be elected: provided always that those who shall be elected as members of the Council resident within such ten miles as aforesaid, shall reside within ten miles by highway or road from the General Post Office, in the City of London, during the whole of the *three* years, or in default of his so doing he shall cease ipso facto to be a member of the Council, but without invalidating any Acts in which he may have concurred after ceasing to be such member.

XVII. And be it enacted, that the Council for the time being shall nominate from time to time in such order as they shall think fit, three vice-presidents from the members of the Council, and the vice-presidents shall continue to hold their office during the presidency of the president in whose presidency they shall have been appointed, if they shall so long continue members of the Council, and if not their place shall be filled up by the Council for the time being; and in every case of the vacancy of the office of president in any manner other than by regular rotation, the first-named or senior vice-president for the time being shall have all the powers of president until another president shall be appointed.

XVIII. And be it enacted, that no one shall be qualified to be elected president, or a member of the said Council of the said College, unless at the time of such election he shall either have been for *ten* years a member of the said College, or unless he shall have possessed the diploma or licence by virtue of which he shall be a member of the said College for at least *ten* years before the election.

XIX. And be it enacted, that whenever any vacancy shall happen either in the presidency or among the members of the Council in any other way than by regular rotation as aforesaid, such vacancy shall be filled by the election by the Council, upon some early and convenient day to be fixed by them for that purpose, of a substitute instead of the person by whom the vacancy shall have been made, and every such substitute shall continue a president or a member of the Council until the time when the person in whose stead he shall be chosen would have gone out of office in regular rotation; and whenever such vacancy shall have been made in the Council by a member resident within such ten miles as aforesaid, the substitute shall be a person resident within such ten miles as aforesaid; provided always that any such substituted member of Council who shall have been elected less than twelve calendar months before the time when the member in whose stead he shall have been elected would have gone out of office in regular rotation, shall be eligible for immediate re-election on the Council.

XX. And be it enacted, that if it shall happen that any election of a president or of any member of the Council shall not be made on the respective days hereinbefore appointed for that purpose, the person or persons then filling the said office or offices shall continue to fill the same until another person or persons shall be appointed thereto; and the president or any vice-presidents of the said College shall, in the manner to be prescribed by the said Council, call a meeting of the members of the said College entitled to vote as

aforesaid, or of the Council, as the case may be, who shall thereupon elect a person or persons to fill the said office or offices so vacant, in like manner as if such election had taken place on the day or respective days hereinbefore fixed for that purpose.

XXI. And be it enacted, that the Council shall have the sole and entire management of the College and of the funds and property thereof, and shall have power to grant diplomas or letters testimonial to all persons admitted into or enrolled in the said College, and to make bye laws, rules, and orders for the regulation and government of the College and of the members and affairs thereof, and for the conduct of the candidates for admission into the College, and for directing the course of study to be followed, and the particulars of examination to be undergone by candidates for admission into the College, and for imposing reasonable penalties, fines, and amerciaments for nonperformance of or for disobedience to the same bye-laws, rules, and orders, and such bye-laws, rules, and orders, penalties, fines, and amerciaments, or any of them, from time to time to alter, change, or annul, so that all and singular such bye-laws, rules, orders, penalties, fines, and amerciaments, be not repugnant or contrary to the laws or statutes of this realm or to the provisions of this Act; and the Council may from time to time appoint, and at their pleasure may remove a treasurer, and a registrar and secretary of the said College, and may also appoint, and at their pleasure may remove such other officers, clerks, and servants as may from time to time be necessary for the service of the College, and shall fix their respective duties and salaries.

XXII. And be it enacted, that a general meeting of the members of the said College, entitled to vote as aforesaid, shall be held within the space of six calendar months after the passing of this Act, at such time and place as the Council shall appoint, for the purpose of considering and reviewing such bye-laws, rules, and orders, as shall be made before that time by the said Council, and of confirming, altering, or annulling the same, as to the same meeting shall seem expedient; and that afterwards an annual meeting of the said members shall be held in the month of in every year, for the like purpose, as regards subsequent bye-laws, rules, and orders, at such time and place as the said Council shall direct; and that other general meetings may be held from time to time as occasion may require and the Council shall direct; and that at all general meetings the President of the said College, if present, and if not the senior or only Vice-President present, or if they shall all be absent, some member of the Council to be chosen by the members of the College present, or if all the members of the Council shall be absent, some other member of the College to be chosen by the members present, shall preside as Chairman, and have a second or casting vote.

XXIII. And be it enacted, that no bye-law, rule, or order, so to be made and confirmed, as aforesaid, shall be of any force until a copy thereof, sealed with the seal of the said College, shall have been laid before and approved by Her Majesty's Principal Secretary of State for the Home Department.

XXIV. And be it enacted, that it shall be lawful for the said Council to make regulations for insuring that in every city and town possessing a medical or surgical school, an annual register shall be kept of all students of the several medical and surgical schools, whether connected with any University, Royal College, Hospital, or other public Medical or Surgical Institution in that city or town, and authorize the taking of a fee for such registration, not being more in each case than *two shillings and sixpence* for such annual registration, and for requiring all such fees to be remitted to the said Council, and returns to be made to them of the registration of all such students, in such manner and form as the said Council shall think fit; and all such fees shall be applied towards the expenses of the Act; and no medical nor surgical student shall be admitted to examination by the said College or Council without certificates of his having been duly registered conformably to such regulations; and that it shall be lawful for the said Council to make regulations for dispensing with such provisions of this Act as to them shall seem fit, in favour of medical and surgical students who shall have commenced their professional studies before the passing of this Act.

XXV. And be it enacted, that the Council shall annually appoint examiners for the purpose of examining those who may be candidates for admission into the said College, and to be enrolled and registered as aforesaid; but no President or member of Council shall be eligible to be appointed an examiner; and at all examinations either the President or one of the Vice-Presidents, or in their absence some member of the Council to be from time to time appointed by the Council for that purpose, shall be present, and shall preside, but he shall not interfere in the examination or have any voice in the admission or rejection of candidates.

XXVI. And be it enacted, that if it shall at any time hereafter appear that any member of the said College shall have obtained his diploma by any fraud, false statement, or any imposition, or that either before or after obtaining such diploma he shall have been convicted of felony, or of having wilfully and knowingly given a false certificate in any case in which the certificate of a medical practitioner is required by law, or shall have wilfully violated any bye-law, rule, or regulation of the said College, then and in every such case, and after such previous notice to or such hearing of such member as under the circumstances of the case the Council shall think proper, it shall be lawful for the Council, with the concurrence of not less than *three-fourths* in number of the members of the Council present at a meeting lawfully summoned for that purpose, to pass such censure or sentence of suspension against the person so offending as to the Council shall seem meet, or wholly to expel such member from the College; and upon any such sentence of suspension or expulsion such member shall cease to be a member of the College, either absolutely or for such time as shall be specified in the sentence of expulsion, and all the privileges granted to such member shall cease and be determined upon such expulsion or during such suspension, and the said Council shall be at liberty to erase the name of such member from the said register; and every such member shall not be entitled to have his name again inserted in any register or published copy without the special licence of the said Council.

XXVII. And be it enacted, that, subject to the reservations hereinafter contained, no surgeon apothecary or general practitioner, after the passing of this Act, who is not registered by the said Council, shall be appointed to any medical or surgical office for the relief of the poor, or in any hospital, prison, infirmary, dispensary, school, workhouse, or other public institution in England and Wales, and whenever by law it is provided that any Act shall be done by a physician, surgeon, or apothecary, or medical or surgical practitioner, by whatever name or title called, such provision shall be construed, after the passing of this Act, to mean a person being either a member of the Royal College of Physicians of England, or the Royal College of Surgeons of England, or being registered under this Act; and the Council shall be empowered from time to time to make regulations for specifying what institutions are to be considered public institutions, and what offices in them are medical and surgical offices within the meaning of this Act; and that all persons who shall be registered by the said Council as surgeon apothecaries or general practitioners shall be exempt, while registered and practising as such, from being summoned or serving on all juries and inquests whatsoever, and from serving all corporeal, parochial, ward, hundred, and township offices; and no surgeon apothecary or general practitioner shall be entitled to such exemption who is not so registered; nor shall the certificate of any such unregistered person, given after the *passing of this* Act, be received as the certificate of a surgeon apothecary or medical or surgical practitioner in any court of law, or in any case by which by law the certificate of a surgeon apothecary or medical or surgical practitioner is required.

XXVIII. And be it enacted, that all persons who shall be registered as surgeon apothecaries or general practitioners by the said Council shall be entitled to demand and take reasonable fees for medical and surgical advice and attendance, and for medicines prescribed or administered by them to their patients, throughout Great Britain and Ireland, and in all other parts of Her Majesty's dominions, without other licence than such registry; and that, after the *passing of this Act*, no person shall be entitled to recover any charge in any court of law, for any medical or surgical advice, attendance, or operation, or for any medicine prescribed or administered by him, unless he shall prove upon the trial, either that he is registered as a surgeon apothecary or general practitioner under this Act, or that before the passing of this Act he was legally practising or entitled to practice in the capacity in which he claims such charge, and if this Act had not been passed would have been entitled to recover such charge in that capacity.

XXIX. And be it enacted, that every surgeon apothecary or general practitioner appointed after the *passing of this Act* to any medical or surgical office for which he is not qualified according to the provisions of this Act, and who shall wilfully or knowingly act or practise in such office, shall for every such offence forfeit the sum of *twenty pounds*, to be recovered by action of debt or information to be brought in any of Her Majesty's Courts of Record at Westminster, or in any County Court, or in the Court of Exchequer in Scotland or in Dublin, within *six* calendar months next after the commission of the offence, in the name of Her Majesty's Attorney General in England or Ireland, or of the Lord Advocate in Scotland.

XXX. And be it enacted, that every person who after the *passing of this Act* shall act or practise as a surgeon apothecary or general practitioner in any part of England or Wales without having been registered as aforesaid, or shall falsely pretend to be so registered, or assume any title as so registered, shall for every such offence forfeit and pay the sum of *twenty pounds*, to be applied to the use of the said College of general practitioners in medicine, surgery, and midwifery, and to be recovered by the said College by action of debt in any of Her Majesty's Courts of Record at Westminster, or in any County Court, or shall be punished by imprisonment, as the Court before which he shall be convicted shall award; provided, nevertheless, that nothing in this Act contained shall extend to render any person liable to any penalty for acting or practising as an apothecary in any part of England who was actually practising as an apothecary on the first day of Angust, in the year one thousand eight hundred and fifteen, or who before the passing of this Act shall have obtained a certificate of qualification to practise as an apothecary from the Court of Examiners of the Society of Apothecaries of the City of London, or who shall have acquired the right of practising as an apothecary by virtue of an Act passed in the sixth year of the reign of King George IV., intituled "An Act to amend and explain an Act of the Fifty-fifth year of His late Majesty, for better regulating the practice of apothecaries throughout England and Wales."

XXXI. And be it enacted, that in the construction of this Act the expression surgeon and apothecaries or general practitioners shall extend to include and mean all qualified persons practising the science and practice of medicine as an apothecary, or the art and science of surgery and the science or practice of medicine, conjointly with or without the art or science of midwifery; and that the word "Council" shall mean the President and Council for the time being; that words importing the singular number shall include the plural, and that words importing the plural number shall include the singular.

XXXII. And be it enacted, that this Act shall be a public Act, and shall be judiciously taken notice of as such.

XXXIII. And be it enacted, that this Act may be amended or repealed by any Act to be passed during the present Session of Parliament.

Correspondence.

ON THE REJECTION OF MEDICAL POLITICS FROM THE EDITORIAL ARTICLES OF THE JOURNAL.

To the Editor of the Provincial Medical and Surgical Journal.

Mr. Editor,—Your leading article of January 8th, involves matter for grave consideration. You are induced to secede from the advocacy of "certain views,

which you have taken of medical politics," although "it is not denied, that those views are *in accordance with the sentiments of the great majority of the Association*," and although "your own impression upon the question is, that in rejecting medical politics from the Editorial Articles of the *Journal*, you will most assuredly impair the efficiency and diminish the interest of its pages." You also lament, "that from the peculiar circumstances in which you are placed, you should have a responsibility, divided between the members of the Association (who claim to be also your directors,) and the profession at large;" and as you "think most decidedly that the *latter* should have the preponderance," you suggest, "if your opinion should not meet with the general accordance of your fellow members, the propriety of altering altogether the form of the *Journal*, and of converting it into a periodical *sui generis*, since its leading articles will otherwise appear to many in the same light as that frequently propounded illustration of inanity—the tragedy of Hamlet with the part of Hamlet omitted."

Now, following out your illustration, it strikes me at first view that there must be something wrong in the state of Denmark, to lead to such a position of affairs as is here presented to us.

You are induced to render the question of Medical Reform a dead letter in your pages for the next half year, at the instigation of some members, "for whose opinion you have the highest respect, who maintain that you have done injury to the Association by sowing the seeds of discord among its members;" and which opinion, (you think, or they think,) is backed by the assertion, that the "Association was established for several *specific purposes*, one of which is the promotion of *harmony* among its members."

It were very desirable at this point to ascertain in reality for what the Association was established? Certainly not for the purpose of being under the directorship or dictatorship of a few individuals behind the scenes, however deserving of respect their opinions may be, or however estimable their private worth. And, certainly not for the purpose of furnishing the professional world with a journal, the Editor of which was not to be allowed the privilege of expressing his "honest convictions" on "any point discussed."

For what, then, was it formed? Let the Council answer. They told Sir George Grey in their memorial of May last, that "2000 members were united together for the *advancement of science, as well* as *the general well-being of the profession*, and, *therefore*, begged to impress upon his attentive consideration that the only principles of Medical Reform, which would be satisfactory to the profession, were uniformity of education, equal right to practise, and the adoption of the representative system in the corporate bodies."

Thus, next to the advancement of science, the general *well-being* of the profession is the *declared* object of the Society, and this is *dependent* on the carrying out of these three most important principles by which it is hoped the members of the great body of the profession will be placed in harmonious relation with our existing institutions, and, in concord and good fellowship with each other. To this end the Society has long laboured;—to these principles they have over and over again pledged themselves at various annual and special meetings, in memorials and reports without number, and on more than one occasion in interviews with the Government authorities.

The *Journal*, under your able management, especially, has borne a distinguished part in support and in furtherance of these principles; and for their promulgation and advocacy you are now accused—save the mark!—of sowing discord amongst the members of the Association.

Can you *seriously* acknowledge the *soft* impeachment? Are the interests of the majority of the members and of the profession at large to succumb to the opinion of the few, however good, however estimable?

Surely there is room for reconsideration before such a step is finally taken. Those who wish, by judicious and temperate modifications, to adjust existing institutions to the requirements of the profession, and form a closer bond of union between the corporate bodies and their members, by which they may be mutually more interested in each other's welfare, will view with sorrow the adoption, on your part, of a proceeding that perils the cause you have hitherto joined them in upholding.

The consequences to the Association I leave to individual members to estimate. That it should become a non-entity, as you describe, in reference to everything connected with the *well-being* of the profession, for the first half year of 1851, or should stultify all its former proceedings, and should seek "inglorious ease" at the very moment when it had made, by the presentation of its memorial of May last, a greater impression than ever on the Government authorities, is so indicative of some discordant element at work, that unless some guardian angel shall interfere with powerful and present aid, we shall have, instead of harmony, "confusion worse confounded."

I speak of the Society and the *Journal* as identical. I presume they cannot, or ought not, according to common sense, to differ in sentiments. We are threatened with a "*contre-coup*;" I hope it may be averted.

I hope the Association may yet assume the distinguished position of demanding from the Government, and carrying out the adjustment of the difficulties, and the reorganization of the profession, according to the principles it has always professed, and by that means preventing a new element of discord being created by the Bill now before Parliament. Such a consummation would afford a much more reasonable prospect of attaining that harmony which it is the object of the Society to diffuse amongst its members, than the suggestions of those who have interfered to effect such a strange and untoward alteration in the conduct of the *Journal*, which under your management has appeared to me as fair, impartial, and as little likely to promote discord, as was consistent with the expression of an independent and "honest conviction" on "any point discussed."

I have the honour to be,
Your obedient Servant,
P. CARTWRIGHT,
Surgeon, Oswestry.

[We have to thank Mr. Cartwright for his favourable opinion, but we must defer any further allusion to the subject to a future number.—Ed. J.]

PROTEST AGAINST THE PROPOSED NEW COLLEGE.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—I take the liberty of enclosing a protest against the proposed new College for insertion in the next number of the *Journal*. I shall be glad to receive the names of those members of the Association who may agree with all or any of my objections, to form a general protest against the obnoxious measure.

I am, Sir, your obedient Servant,

C. R. BREE.

Stricklands, Stowmarket,
Jan. 16, 1851.

PROTEST AGAINST THE ESTABLISHMENT OF A ROYAL COLLEGE OF GENERAL PRACTITIONERS.

1.—Because I consider that the *status* of the English medical practitioner will be lowered by the institution of a new College, which would perpetuate the evils under which he now labours, and equalise the *locus standi* of a body of men who at present are, by difference in ability or study, manifestly unequal.

2.—That it would be unjust to oblige members of the Royal College of Surgeons to sink their present rank in that of an unfair College, into which it is proposed to admit, indiscriminately, those who possess inferior qualifications.

3.—Because I consider the only way to raise the standing and the usefulness of the medical profession, is by raising the standard of qualification for general practitioners at least as high as that required for the candidates of the M.B. degree in the University of London, and by separating entirely the scientific from the trading part of the "Art and Mysteries of Medicine."

4.—Because I consider that an Examining Board, formed jointly by the Royal College of Physicians and the Royal College of Surgeons, or elected by them, would be amply sufficient to examine all candidates for the degree which would entitle them to practise under the several titles of M.D., (physicians,) S.D., (pure surgeons,) and M.B., (general practitioners)—the examination for all being the same up to M.B.—and a step higher for those wishing to take the standings of physician or surgeon respectively.

5.—Because I consider that all the quarrelling and party feeling created in the profession arises from a morbid desire to disturb existing institutions, and to raise upon their ruin an inferior College to either, which would in its turn be liable to similar attacks by men of the same class, and would thus perpetuate the great evil of medico-political agitation, which is alike reflective upon the honour and respectability of the profession, and derogatory to the science of medicine.

6.—In addition to the above reasons I protest against the establishment of a College of General Practitioners, because it will be unsatisfactory and obnoxious to a great majority of the existing practitioners in medicine,—because it will fail to settle the question of Medical Reform,—because it is unjust towards the existing Colleges to which the science of medicine already owes so much,—because it is not wanted in the profession, and because it will be positively injurious to its best interests, and destructive of the harmony which ought to characterise and distinguish its members.

Charles Robert Bree, M.R.C.S.

Stowmarket, Suffolk, Jan. 15, 1851.

THE CENSUS OF 1851,

IN RELATION TO PUBLIC AND PRIVATE LUNATIC ASYLUMS.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—As the subjoined correspondence between myself and the Registrar-General will be read with interest by a large class of professional gentlemen, associated with public and private lunatic asylums, I offer no apology for transmitting it to you for publication in your *Journal*. It certainly would have been most unjustifiably inquisitorial if the proprietors of private asylums for the insane had been compelled to make a return of the *names* of the patients placed in confidence with them.

I remain, Sir, your obedient Servant,

FORBES WINSLOW.

Dec. 9, 1850.

Sir,—I perceive by the printed form of the census for 1851, issued, I believe, under your authority, that it will be necessary for each householder to make, agreeably to a prescribed tabular form, an accurate return of the Christian and surname, age, occupation in life, &c., of each person sleeping under his roof on a special night. As I am much interested in behalf of a numerous and influential section of the medical profession, viz., those engaged in the cure and treatment of the insane, may I be permitted to ask, whether the resident proprietors, or medical superintendents, of private and public asylums will be required to make a return of the *names of patients placed under their care*, and actually resident with them at the period when it is proposed to take the census? Your early attention to this matter will much oblige, sir,

Your obedient Servant,

Forbes Winslow, M.D.

To the Registrar-General,
Albemarle Street, Dec. 5, 1850.

Census Office, Cray's Court,
December 9, 1850.

Sir,—In reply to your letter of the 5th instant, I have to state that I should think that, rather than return the *names* of all patients in lunatic asylums, it may be sufficient if the initials of their names be recorded when the census of 1851 is taken, to which I should think there would be no objection.

I have the honour to be, Sir,

Your faithful Servant,

George Graham,
Registrar General.

To Forbes Winslow, M.D.

DR. WOODFORDE ON THE REPORT IN THE LANCET OF HIS CASE OF OVARIOTOMY.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—Since you published, (in the number of this *Journal* for October 30, 1850, page 598,) the report of the successful case of ovariotomy at the Taunton and Somerset Hospital, which was read by me at the autumn meeting of the Bath and Bristol Branch, a different version of the same case has appeared in the *Lancet* for December 21, 1850.

I shall feel obliged by your permitting me to state, in justification of the report read by me at Bristol, what will perhaps be hardly credible to those who have seen it in the *Lancet* only—namely, that the case was under my sole care, from the date of admission until January 25, 1850, when, in consultation with the hospital staff, my proposal for the operation was adopted. I will add that my report, which was drawn up from careful notes made by Mr. Gaye, the house-surgeon, was by previous mutual agreement submitted to my colleague, Mr. Cornish, who performed the operation, and approved by him, before I read it at Bristol.

I did not intend to obtrude a purely personal matter of this kind on members of the Association, but the appearance of the report from the *Lancet*, somewhat abridged, in two of our local newspapers (!) has compelled me to break silence, and I hope that the exposure of such breaches of professional etiquette and courtesy may help to do good.

I am, Sir,

Your obedient Servant,

FRANCIS HENRY WOODFORDE, M.D.

Physician to the Taunton and Somerset Hospital.

Taunton, Jan. 6, 1851.

Medical Intelligence.

SELF-SUPPORTING DISPENSARIES.

A very numerous meeting of the medical men of the town and neighbourhood of Reading was held at the Great Western Hotel, on Wednesday evening, Dec. 18th, to hear an exposition of the system of *self-supporting dispensaries*, by Mr. Smith, their benevolent founder. He very ably demonstrated their benefits; and though no distinct resolution was come to, it was the opinion of the meeting that, if properly founded and superintended, their establishment would be fraught with many advantages. A vote of thanks was unanimously passed to Mr. Smith, whose life appears to have been, and to be, devoted to acts of charity and measures of philanthropy.

QUARANTINE.

Dr. Babington has been requested by Lord Palmerston to attend, on behalf of the British Government, the meeting of medical men convened at Leghorn by the Austrian and Italian States to consider the subject of quarantine.

IRISH MEDICAL CHARITIES BILL.

A large and important meeting of the profession in Ireland, and interviews of their deputation with the Earl of Clarendon and Sir W. Somerville, were lately held.—*Lancet.*

OBITUARY.

Lately, at Boston, John Brown, Esq., M.D., aged 51. The deceased terminated his existence by taking prussic acid. The body was found in the hot-house, and was in a sitting posture, with one arm resting upon a flower-pot. A short time ago the deceased held the office of Mayor, and was a magistrate for the borough. An inquest was held on the body, and the Jury returned a verdict of "temporary insanity." About fifteen years ago, an eminent surgeon, who had filled the office of Mayor, took prussic acid, and died in the same way.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted Members on Friday, Jan. 10th, 1851:—James Bain, Hon. E.I. Co.'s Service, Bombay; George R. Bull, Birmingham; John Bunney, Coventry; Gideon James William Griffith, Mountpleasant Square, Dublin; William Dixon Grahame, London; Henry Brougham Hillcoat, Brussels; Patrick Dillon Kelly, Mullingar, county Westmeath; William Henry Paine, Stroud, Gloucestershire; Alfred Puddicombe, Moretonhampstead, Devon; William Palmer Steele, Abergavenny, Monmouthshire; Henry Thomson, Belfast; Harry Speakman Webb, Oxford.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Members on Thursday, Jan. 2, 1851:—Henry Parker, Sheffield, Yorkshire; Oliver Cooper Pollard, Chorley, Lancashire; Charles Robert Thompson, Westerham, Kent; John Doxon Ward, Manchester.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

NOTICE TO MEMBERS.

Members who wish to propose Associates are reminded, that as the subscription commenced on the first of January, it is the most convenient time to introduce new members.

It is also particularly requested that all post-office orders should be sent either to the Treasurer or Secretary, who alone have the power of giving receipts.

JAMES P. SHEPPARD, Secretary.

Worcester, Jan. 21st, 1851.

Erratum.—In Mr. Foster's "Cases of Fever, with Remarks," inserted in our last number, page 14, col. 1, line 6 from the bottom, for "Huntingdon," read *Hemingford.*

TO CORRESPONDENTS.

Communications have been received from Mr. Willis, Mr. King, Dr. Robertson, Mr. Moncton, and Mr. Pritchard.

Mr. Humphry's communication arrived too late for insertion, having been misdirected to Cambridge.

Mr. Foster's proof did not arrive till the day *after* publication, we could not, therefore, insert the corrections.

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho.

CLINICAL LECTURES

ON THE

PRACTICE OF PHYSIC,

DELIVERED IN THE

THEATRE OF QUEEN'S COLLEGE, BIRMINGHAM, 1849-50.

By DAVID NELSON, M.D.,

Physician to the Queen's Hospital, and Professor of Clinical Medicine, &c.

[Reported by MR. WILLIAM ROGER BANKS, Student of the College and Clinical Clerk.]

LECTURE I.

On the General Physiognomy in Disease.

Gentlemen,—Before proceeding to descant upon the various individual diseases as they may accidentally present themselves at the Queen's Hospital, I shall first endeavour, by a series of general lectures, to lay before you a methodical view of the sundry ailments to which the principle organs of the body are liable, illustrating those ailments by the citation of actual cases, most of which you yourselves will have had the opportunity of watching within the walls of the institution. By the adoption of this mode as an initiatory proceeding I conceive that you will attain a much clearer apprehension of those great principles upon which the practice of physic ought to be conducted, and also habituate your minds to a regular system of clinical study, instead of frittering your energies upon desultory observations—now in one line of diseased action, now in another, before you have fairly arrived at that mastery of general pathology by which we are enabled to blend so many sciences into one, to view composite truths as unities, and reduce, if I may so speak, the various prismatic rays of fact to the one sun-ray of philosophy. Without this power of synthetical reduction you must remain mere empyrical routinists; but before you can attain it you must first study details in all their complexity, and in as orderly a manner as you can. You must have analyzed before you can synthetize. He who announces a great principle, simple as it may seem, must first have taken to pieces whole pyramids of facts; and not only so, but have noted also the exact relation which each one bore towards the rest. This alone is sound learning—this alone is the province of true genius; for it is not to him who gives birth to a thousand dazzling errors that the palm is to be awarded, but to him only who stedfastly marches in the straightest line to truth. Moreover, on the truth being arrived at it must, in order to be available, not merely remain as a cold abstraction, but as a living familiar guest, which must become identified with the natural faculties, to be moulded or wielded more easily in our daily practice than are our garments in our daily walks. Let any one consider the millions of facts which constitute the bases of mathematical, chemical, and natural science, and he will at once perceive how essential such a generalizing and self-appropriating power must be to him who is so often called upon at a moment's notice to apply his complex deductions to the most intricate structure in creation—a structure which, in its anatomical arrangements merely, demands almost the study of a lifetime. No wonder, with such Herculean labours before them, and such a necessity for combining judgment and genius in one mind, that so many men should have borne the title, without being able to exercise expertly, the function of physician. This is said not to discourage effort, but to increase it. Fix your attention upon the two great parts of life and death, and mark, at the same time, how every other occurrence in nature, either external or internal, may tend to support the one, or induce the other, and thus you will possess a balance for estimating the relative value of a therapeutical genius, which shall be applicable at all times, and under all circumstances.

Before entering upon the different affections of particular organs, I shall take a review of the physiognomy or general expression of the body under disease. It presents certain appearances well worthy of attention, which were wont to be studied by Hippocrates and the older physicians, including our own Sydenham, &c., much more assiduously than they are now, when unfortunately a prevailing passion for mere physical diagnosis, has blinded an otherwise acute age against the perception of sundry evidences of morbid action, which are, nevertheless, quite as palpable as the solid signs themselves. A judicious physician will take the full advantage of both. To set aside the subjective symptoms, and all the bodily expressions that attend their presence, and to look for objective symptoms only, would be simply to treat the later, while we passed over the earlier stages of maladies, and would afford proof that we had allowed the secondary or tertiary changes to run on which might otherwise have been prevented. There are sometimes appearances in the countenance, and on the surface of the body, that without being traceably connected with any particular internal organ, shall yet prove indicative of the disorganization of such organ. Yet there are certain persons who have assumed to themselves, in an exclusive sense, the reputation of pathological physicians, upon no other ground than that they profess to found their opinions on physical evidences alone. But they forget that in thus confining themselves to a physical diagnosis, and omitting to estimate the value of those nicer symptoms of disease, they are simply confounding the science of pathology, which is the doctrine of the laws which connect the cause to all the accompaniments and consequences of diseased action, with the merely descriptive statements of morbid anatomy. The latter confines itself to mere material facts, the more solid results of previously disturbed function, while the former seeks to investigate the nature of the non-visible preceding disturbance, with a view to discover counteracting influences. The laws of pathology have the same relation to morbid anatomy which the laws of physiology have to ordinary growth, and whilst a knowledge of the latter in the hands of the sound physician ought to lead to the full development of healthy structure, so a knowledge of the former should tend to prevent the production of morbid growths or deposits, instead of merely groping for their

discovery after their formation has been effected, while the physical discharges therefrom, which may be generally considered as pathognomonic, are absent; such observations are, therefore, of high importance, and ought never to be neglected.

When a patient is first presented we naturally take note of his general aspect as to complexion and temperament, because we know that each temperament is prone to certain ailments, and that each ailment will be modified by temperament. The sanguine is liable to high inflammatory action; and any irritation is very likely to excite a commotion in the system that will require depleting measures. The melancholic is less easily moved, but when stimulated by powerful or persistent causes may very likely assume a strong and enduring form of reaction that may constitute chronic disease. The nervous is weakly and highly exciteable; the slightest causes will produce a derangement of function too rapid and sudden to invoke any organic change, while tremblings, convulsions, palpitations, and a thousand other evanescent disturbances will perpetually demand our regard, the main resources being tonics and sedatives. The phlegmatic is both insensible and lax; it will not easily be moved to acute action, but when its feebler powers become reduced there will likely take place a tendency to cachectic degeneration; anæmia, dropsy, mollification of the heart, rickets, and œdema of the lungs, will be some of the probable attendants; and our treatment must be based on moderate stimulants and full nourishment, whatever else we may employ at the same time. The complexion is in a great measure associated with the temperament: in the sanguineous, fair and ruddy; in the melancholic, dark; in the nervous, pale, or it may be tinged with red; and in the phlegmatic also pale and likewise tinged with red, and puffy at the same time. There may be hues of complexion, however, more distinctly allied to actual diseased action; as the yellow, under absorption of bile, the deadly pale in anæmia, and likewise the green colour that accompanies the same complaint, under the name of the green sickness; the dust colour that attends certain forms of malignant action, as well as the straw colour that attends others; the heavy flush of fever and pneumonia; the blue of cholera and other deoxidysing complaints; and the peculiar doughy aspect and Flemish expression in albuminuria. All these are of so decided a description that they excite an instantaneous conviction in the mind of the experienced physician as to the nature of the malady, as instanced respectively in the cases of A. B., jaundice, No. 1; D. C., anæmia, No. 2; E. F., cancer, No. 3; of G. H., cancer, No. 4; fever and pneumonia, 4 and 5; cholera, No. 6; and albuminuria, No. 7;* the latter being especially deserving of attention, as proving the very important fact that Bright's disease was diagnosticated as correctly as in other cases in which no albumen was discoverable in the urine. (There was enormous hypertrophy of the heart, weight four pounds and a half, with calcareous vegetations.)

Another feature that will be noticed on the first visit of a patient is the manner in which he enters the room. He may advance with the uneasy stoop of thoracic or abdominal disease, or with the slow pace of headache, with the stiff shuffling of confirmed secondary rheumatism, the drunken-like stagger of partial paraplegia, the eccentric wriggling of St. Vitus's dance, in those sprawlings of the feet, accompanied with sudden bendings forward and equally sudden arrest of motion, which usher in the dreadful irritations of general paralysis or mania ending in dementia. The condition of the hair will be observed at the same time, whether it have the crisp and moist appearance of health, or the lanky, split, and withered appearance of disease. There may be the thick close growth of habitual headache, the spare growth and downy whiskers of the phlegmatic cachexy, the baldness of hereditary local weakness or of dissipated habits, and the not unfrequently luxuriant locks of phthisis.

The brow is also a conspicuous object of remark, especially as regards its wrinkles, which, if they be not the effect of old age, will have resulted from long-continued suffering, either due to the feelings connected with chronic toil, especially under a glaring sun, or chronic disease. This applies more especially to the perpendicular wrinkles over the nose, which if found in the young are seldom to be attributed to any idiopathic irritability of temper, but rather to the cause latterly indicated. They are to be observed under the organic sufferings of typhus and other stupifying diseases; in all internal chronic ailments which involve organs not associated with much cerebral sensibility, as the liver and lungs; and may then be as marked in children of a few years old, as in the aged and infirm. The lateral wrinkles are of much less consequence in a medical point of view, though they may be a familiar index of age, of toil, of anxiety, of dissipation, or of diminished plumpness.

The eyes in their colour and general expression will be found in accordance with the temperaments, but there are besides certain peculiarities associated with certain diseases. We have the yellow hue of jaundice, the puffiness of albuminuria, the specks of ancient syphilis, the heavy suffusion of cerebral hyperœmia, the not uncommon brilliancy of phthisis, and the ghastly glitter of uterine carcinoma, independently of those features which may be presented to us, when the organ is of itself affected with idiopathic disease, or with the natural expressions proceeding from excitement or madness. The inability to look properly and fairly in the face of the auditor, has been attributed by Dr. Alison and others to a consciousness of improper habits not fit to be named.

Although the nose, from its frequent grandeur of outline, has been dignified by professed physiognomists and their exponents, the sculptors and painters, into a feature expressive of the highest qualities of mind, it is yet an organ of little mobility, and therefore cannot afford much indication of alteration of shape under disease. Yet few can have avoided observing the fact, that it becomes sharp and pinched after fever or any other exhausting attack, and in the course of

* The cases referred to above will be given in an Appendix to Lectures.

phthisis or diabetes; equally observable is its occasional scabbiness in struma, its redness in chronic dyspepsia, and above all, as the most important feature, its dilatation in those diseases of the heart or lungs when life is in imminent danger. I am not aware that the appearances of the ear are of any general significance, except that the cracking of the skin along the hollow at the back of it, accompanied with a muco-purulent exudation, indicates an imperfect condition of the stomach and bowels mostly characteristic of young children. It may also be mentioned that there is a defective development of the external ear, accompanied with a receding chin, which usually give evidence of a congenital defect in the nervous organization.

The external mouth or lips afford us several *criteria*, by which we may judge of certain constitutional affections; thus in hemiplegia it will be twisted towards one side, in anæmia and albuminuria very white, while in cholera and pneumonia, or in any other attack involving defective arterialization of the blood, it will be purple or blue. Large lips, inclined to scabbiness, and fissured in the centre, will indicate a congenital insufficiency of development, usually connected in after life with struma. In fever the lips will be dry and cracked, and the skin will peel off them, either of a white, a brown, or of a black colour, according to the type which it assumes. There are also flat pustules of a specific character, which are sometimes to be noticed in the course of syphilis, and in young persons, there are frequently ephemeral eruptions of a less important kind, which give warning of vitiated secretions and other consequences of mal-assimilation requiring the aid of mercury or other medicines in alterative doses.

Before the patient is seated some inferences may be drawn from his general conformation of frame. We may see the short thick neck and full stoutness of threatened apoplexy, or the broad flattened chest which is so often associated with cardiac hypertrophy. There may be obesity or leannesss, each pointing to very opposite conditions of the general system, the first showing an exaltation of the nutritive process, totally inconsistent at least with phthisis, though frequently combined with cardiac disease; and the second proving a defective reparation, which may either be due to true degenerate action, or to simple waste or starvation. We may have the bent bones of rickets, which are always an evidence of weakness in the young subject, though frequently and indeed generally clothed with vast layers of muscular fibre in the adult; as to the long neck, high cheek bones, drooping shoulders, narrow breast, and protruding scapula of phthisis, they form a picture too familiar to need further description. After the patient is seated we must naturally observe the condition of the skin; it ought, irrespective of complexion, to possess a soft and gently moist surface, not inconsistent with the hardy roughness which usually betokens rude health. A dry, sharp, and cracking surface will prove some malassimilation. Moisture, especially if cold, will show that there is relaxation of the exhalents. Dark blotches will prove an over fluidity of blood, or else a greater degree of the above relaxation. In cholera we shall have a general blue, in scarlatina an universal red, and in jaundice an universal yellow. Heat of skin will make us predicate fever, whether idiopathic or sympathetic, and if that heat be mostly apparent over the scalp, it must be referred to a hyperœmic condition of the cerebrum itself, dependent on a previous affection of the lesser intestines. Certain odours may also be perceived arising from the cuticular surface of morbid bodies, on a close approach, that are of considerable importance. Thus there may be a bilious smell discoverable in those who are habitually constipated, a decidedly acid aroma is perceptible under gout and rheumatism, there is a strongly urinous odour which proceeds from the perspiration of those who are suffering from retention of urea in the system, and also a peculiar earthy smell that hangs about the bodies of those who are dying from long-continued and exhausting diseases, as phthisis and dysentery. The nails and their attachments are likewise important objects of observation. They ought in perfect health to be soft, smooth, and tough, and of a beautiful pink colour, but may become altered in these respects, under scarcely appreciable changes in the constitution of the fluids. Thus the nails may become blue on account of their situation, under very slight degrees of cold, and there are in like manner very slight deviations from health which will cause them to be dry and brittle contemporaneously with some harshness of skin and lankiness of hair. In cholera and other diseases of defective oxygenization they will become intensely blue; under tubercular degeneration they will often shoot out in an extraordinary manner and show a tendency to incurvation; the points of the fingers at the same time may become hypertrophied; but more especially there will frequently be seen a stretched and brown shining appearance of the skin immediately investing the root of the nail, that may almost be said to be pahthognomic of that very fatal diathesis long before it manifests any action upon the lungs. In conclusion, I may only further allude to one feature that often characterises the general surface of the body, along with the more immediate envolutions of the mucous surfaces, inclusive of the organ of special sense, and that is an exalted irritatability which gives rise to shrinking, moaning, and even wild shrieking, under the slightest application of any stimulus. This will always be found attendant on nervo-cerebral affections, and may be exemplified in hysteria, adynamic fevers and injuries of the brain. In the latter class of cases this state of body may be witnessed even at times when the patient is almost in a state of coma as will be illustrated in the cases of Bayley. The first under typhus fever, the second under cerebral effusion.

All these points, which have taken me some time to describe to you at length, are presumed to pass through the mind of the practised physician as rapidly as the eye can receive the impressions of them, and may scarcely occupy one half minute of the interview. In the busy avocations of life, when men are called upon to act as well as to think, they must acquire some celerity and adroitness of observation and reflec-

tion, or else retire from the field. This applies more especially to the higher members of the military, naval, and medical professions, who are left in confiding hope to their own pure discretion. They must lose no time in coming to a decision, for whilst they deliberate, their respective enemies of battle, tempest, or pestilence, may be acquiring an irresistible impetus. They must, under the worst emergencies, take the largest view they can of the state of affairs, and draw the most rapid conclusions; yet not, (as already observed in the introductory lecture,) that this rapidity is any rapidity at all, unless the conclusion be correct. For speed is something very distinct from mere haste; the one being the measure of our progress, the other of our effort. The physician must be calm and collected under the most alarming symptoms, or he is unworthy of his high vocation. His whole powers must be earnestly bent upon the issue of his case without any fear of that issue disturbing the equable exercise of his faculties. The more certain his knowledge, the more consistent and uniform will be his line of march; and that march, if guided by true wisdom, will rather be effected by long deliberate strides than by hurried and shuffling efforts.

OBSERVATIONS ON

HYDATID DISEASE OF THE LIVER.*

By P. M. DUNCAN, M.B.,

PHYSICIAN TO THE ESSEX AND COLCHESTER HOSPITAL.

PART II.

Descriptive and Minute Anatomy of Acephalocyst Hydatids; Theory of their Entrance into the System; Remarks upon their Generation, Development, Distribution, Progress, and Decadence.

In the liver an hydatid tumour invariably consists of a more or less dense and laminated fibrous globular sac, which is lined, internally, by a delicate albuminoid membrane, rendered tense by a limpid colourless fluid. This last is the parent sac or acephalocyst; it occasionally contains many smaller ones, which in their turn may contain others.

Echinococci are always to be found in human hydatids. The external fibrous sac is non-essential, and consists of altered liver structure; its thickness varies from two to ten lines, according to the age and situation of the hydatid. It is always roughly laminated, the external lamina being in close connection with the liver, the internal being in simple apposition with the albuminoid cyst, which constitutes the true hydatid. The microscope discovers in this external membrane, besides altered blood-vessels, and bile-ducts, much white fibrous tissue; there is a considerable vascular connection between the masses of this fibrous tissue and the surrounding liver structure, which is always more or less affected by the gradual pressure of the acephalocyst.

In very old and thick fibrous sacs, phenomena occur which interfere with the growth, and frequently with the life, of the hydatid which they cover. The innermost layers of their laminated structure become more and more removed from the pale of nutrition, and changes happen which appear to be independent of the vitality of the tissue; masses of crystals of a carbonate, and of cholesterine are found betwen the layers, and much exudation-matter in their substance and surrounding the blood-vessels which supply them. After a time these adventitious products increase to such a degree as to bring about changes in the acephalocyst itself, which gradually loses its fluid, and finally collapses, and after death is found beautifully folded up within the altered fibrous sac. The innermost layers of the fibrous sac are the most affected by the above-mentioned changes; and we find that large masses, of the consistence and aspect of putty, are occasionally thrown out from the free surface of the innermost lamina into the space between it and the acephalocyst, and the microscope discovers them to consist of crystals, oil globules, and exudation-bodies. In those subjects where the general nutrition is weak, especially in aged people, these deposits are most common. I have lately met with a fibrous sac of an hydatid, which in some spots was of osseous hardness.

From careful examination of the structures of the fibrous sacs of acephalocysts, I am inclined to believe that an atheromatous condition of the walls of the blood-vessels which supply them, invariably exists before the deposit of adventitious matter occurs. It would appear that, whenever from any cause the growth of the acephalocyst is stopped, and the office of numerous blood-vessels is of course at an end, that nature immediately commences operations which tend to their decadence and final obliteration. From some cause with which we are unacquainted, certainly not from an inflammatory one, but rather from some perversion of nutrition, a deposit of oil globules occurs beneath the internal lining membrane, and in the tissue of the middle coat of the smaller blood-vessels; cholesterine crystals are subsequently formed, and their calibre seriously interfered with. Soon, and especially if these deposits of atheroma exist to any great amount, the walls of the blood-vessels permit the transit of a considerable quantity of colourless blood-plasma; they have lost the power of antagonising the disposition to excessive exudation. Now, this exudation of plasma is totally different in its causation and subsequent development to that which owes its existence to inflammatory action; no tissues are formed from out of it, no cell-growth occurs; on the contrary, the plasma seems to lose the greater part of its vitality, its watery parts deposit crystals; oil, always typical of vital degeneracy, is found, and the only trace or evidence of life is in the abortive development of masses of exudation-bodies, which consist of myriads of very small and highly-refractile globules, in all probability nearly allied to fat, and at all events highly carbonaceous. These products of exudation press upon, and obliterate, many capillaries, and influence, in a secondary manner, the

* Continued from page 656 of last volume.

nutrition of the acephalocyst. It appears that in order that these changes should occur, either there must be some cause which prevents the acephalocyst assimilating the colourless blood-plasma by which it is nourished, and which necessarily retards its growth, or else that the powers of life, generally speaking, are on the wane. We find corresponding exudation from diseased vessels in the arcus senilis, in white softening of the brain in old people, and in the middle-aged like deposits occur from constitutional causes, and a perversion of the nutrition of the affected part. The exudation in the layers of large aneurisms is well known. The semi-transparent albuminoid membrane which lines the internal surface of the fibrous sac, is the true hydatid; it is not formed by altered liver structure, but consists of a tissue peculiar to itself, which, although nourished within, yet is not the product of the organism.

Whatever may be the size of the albuminoid membrane or acephalocyst, it is always, except when in its decadence, tense with fluid; it may or may not contain others like itself, and produces from the surrounding tissues, by the pressure incident to its growth, the fibrous sac. In colour the acephalocyst is generally of a blueish tint by transmitted, and of a pearly colour by reflected, light; it is in contact with the fibrous sac, but there is no organic connexion between them; it is perfectly extra-vascular, and yet is nourished by the exuded plasma of the capillaries of the lamina of the fibrous sac nearest to it.

The microscope reveals some very interesting facts in the structure of the acephalocyst; upon using a magnifying power of 600 diameters, or even much less, with the aid of a not too brilliant transmitted light, a thin section parallel to the diameter of the acephalocyst, and placed in water, presents a series of lines of most extraordinary delicacy, number, and regularity. These lines occur in pairs, the distance between the lines constituting the pair being very small, but the distance between the pair of lines on each side of any one is more considerable. So that commencing with the periphery and passing inwards, we find first of all, a single line, then a considerable distance, then a pair of lines, then a considerable distance and a pair of lines follows, and so on till the inner surface of the acephalocyst is reached. Here the structure ends by one line. No structure or lines of any kind, are to be seen in a section parallel to the circumference. By breaking up the first section mentioned, we discover that the acephalocyst consists of many scores of concentric layers, each layer is a cyst, and has a layer on its out and inside, the connexion is that of simple apposition only, but is a very close one. The two edges of each layer or lamina are closely applied to corresponding edges of other lamina, there results then a pair of lines, *i. e.*, the proximated edges of two laminæ, then a space free from lines, of some considerable dimension, the structure of the lamina, and then two more lines, the one being the edge of the lamina and the other being the edge of another in apposition with it. The outside of the outermost lamina is in apposition with the inside of the fibrous sac, and its inside is in contact with the outside of the next lamina, and so on; the outside of the innermost lamina of the acephalocyst, is in contact with the lamina next external to it, the inside is washed by the fluid of the interior. The laminæ vary in number according to the age and size of the acephalocyst, which probably in its earliest stage of existence, simply consisted of one lamina. It appears to me that the layers are developed eccentrically, both because the innermost layers are in old acephalocysts, frequently the seat of a crystalline deposit, and because the two innermost layers perform an office which is peculiar to them, they having to do with the generation and development of the secondary acephalocysts, (those floating in the fluid of the acephalocyst) and of the echinococci.

The laminæ are homogeneous in structure, no markings of any kind are to be found in them by the highest powers of the microscope; they are readily permeated by their nutrient fluid, but seem to resist the outward passage of the fluid contained in the centre of the acephalocyst. They would also appear to assimilate the albuminoid principles, and to allow the aqueous part of the blood plasma to pass into and mix with the central fluid. The external laminæ are thicker than the most internal. When the acephalocyst contains fluid and echinococci alone, it is said to be simple, and when other cysts are found within it, we call it compound, and these cysts are said to be secondary. The secondary acephalocysts resemble the primary or containing cyst in structure, they are globular, except when mutual pressure causes them to take on some other form, and contain a fluid like that in which they float, echinococci and occasionally other cysts like themselves. Their contact with the parent cyst, is occasionally necessary for their existence by nutrition. The fluid of the acephalocyst is limpid, colourless, saline, and has a specific gravity which averages 1010, common salt, an animal matter, and, according to Dr. Budd, "a trace of other saline matters, probably all the salts of the blood not associated with its albumen, and water, enter into its composition. The fluid is generally in sufficient quantity to render the acephalocyst very tense; it is, however, liable to absorption, when the nutrition of the fibrous sac and of the acephalocyst suffers. Occasionally floating about in the fluid, but more frequently at the bottom of an hydatid sac, we find numerous ovoid, pearl-coloured bodies of the size of a very small pin's head. The microscope proves them to belong to the lowest tribe of entozoa, and to be, and merit the name of, echinococci.

Livois asserts that echinococci exist in all acephalocysts; and Dr. Budd and Mr. Busk have invariably met with them. Formerly their existence was supposed to be a matter of accident, and by some they were thought to be parasites of their enclosing cyst. To the naked eye they are just visible, and are of a pearly white colour; found attached to all parts of the internal surface of the true acephalocyst; they also float in great numbers in the fluid, which does not, however, appear to be their proper place, as the circlet of hooks with which each is furnished, indicates an existence more or less stationary and fixed.

Owen asserts, on the authority of Müller and Quekett, that the echinococcus hominis differs from those of the hog, in having suctorious cavities beneath the circlet of hooks, and visible when this is protruded. Dr. Budd says that these suckers have not been visible in any specimens he has examined, whether taken from human hydatids or from those of the sheep. I must add my humble testimony to the same effect. The well-known accuracy of the two first-mentioned observers, forces us to believe that there is more than one kind of echinococcus, viz., those having suctorious cavities, and those in which they are absent.

The following is Dr. Budd's description of the kind he and most others have seen:—"Echinococci are oval, transparent, colourless creatures, somewhat egg-shaped, and presenting under the microscope a distinct double outline. The anterior end has a depression or cleft, from which there is an evident canal or mouth, leading to a circlet of hooks which is within the body, and nearer the posterior end than the anterior. The posterior end has also a slight depression, which has now and then a fibrous pedicle attached to it. The creature is studded with globular bodies, which from their refracting light strongly, have under the microscope a strong dark outline, and a bright centre. They seem to be in the membrane of which the body is composed, or rather between the outer membrane and an interior solid body, and are at different depths from the object-glass, so that while some are clear under the microscope, others are indistinct."*

I have not detected any muscular or nervous structure in the creature, the circlet of hooks is retracted by the irritability or rather the contractile nature of the surrounding parts. After the death of these creatures, during decomposition, the circlet is protruded; whilst they are attached to the cyst-walls such is also the case; the stimulus of light, however, excites the contractility of the tissues which retract the circlet, and we see them with the row of hooks in the centre of their body. It would appear that the protruded state was the natural or usual one, and that only under peculiar circumstances, owing to an unusual stimulus, or before perfect development for instance, the circlet is retracted. The hooks or teeth of which the circlet is composed, are generally between twenty or thirty in number, they are hard, and resist decomposition, resembling somewhat the iron part of a pickaxe in shape, they have a sharp and a blunt extremity, and there is a tubercle in the centre. The teeth are fixed around a circular base, the sharp end points posteriorly, so that when the circlet is plunged into the albuminoid texture of the cyst, it is not very easily removed.

The echinococci have not been discovered elsewhere but in acephalocysts, primary or secondary; they appear in these last very shortly after they have become visible to the naked eye, and as the cyst increases in size, so do its inhabitants increase in number.

The organization of the echinococci is very simple, and their place is also very low in the animal scale; they do not always present the refractile globules beneath the superficies. In one of the cases I have described there were none to be seen, but in considerable numbers, in the vicinity of several echinococci, there were globular cells, some refractile, others presenting a granular mass in their interior. In this case the fluid of the acephalocyst had become absorbed, a simple halitus remained, and numerous echinococci and these cells were found congregated wherever there was a slight excess of moisture. Now, as the acephalocyst must have been in the state described, for at least fifteen years, it becomes interesting to observe the great latent powers of life possessed by these entozoa, a peculiarity almost equalling that of the rotifera. The refractile globular bodies I believe to be ova, of whose future destiny I shall presently treat.

[To be continued.]

DEATH CAUSED BY THE INHALATION OF CHLOROFORM.

By EDWARD JACKSON, Esq.,

Demonstrator of Anatomy at the Sheffield Medical Institution.

J. S. aged 21, a young man studying for the medical profession, of a reserved disposition, but at times immoderately cheerful. Has enjoyed tolerable health throughout life, although suffering very frequently from toothache or tic doloreux. A week previous to his death he sustained a great loss in the death of his master; this threw into his hands a more than usual amount of labour, and he appeared somewhat anxious as to the course he should pursue in carrying out his studies, but there was no evidence of any remarkable depression of spirits. He had been accustomed at various times, when he suffered from toothache, to inhale chloroform on a pocket handkerchief, but in the presence of the servant man, to whom he gave instructions to arouse him, if stupor continued beyond a certain time; he had also been accustomed to take small quantities of opium at bed-time, being subject to restlessness and disturbed sleep.

On the 23rd of June he followed his customary avocations, and in the evening went to church, and from thence accompanied a friend to supper. Although he complained of not being in his usual health, still there was nothing to attract attention, and he parted from his friend cheerfully, promising to meet him the following evening. He had partaken, for his supper, of veal and tart, with a little sherry, and retired to rest at half-past eleven. At a quarter to twelve, a gentleman, (Mr. R.,) who occupied a bed in the same room as the deceased, retired to rest. The deceased had extinguished his light, and appeared to Mr. R. to be in a sound sleep. The latter got into bed without taking further notice, and after a period of fifteen minutes, he heard a moan, which he regarded as nothing unnatural, or probably, he thought, the result of dreaming, and fell

asleep. He arose at six in the morning, and having finished his toilet, went out for a walk, leaving, as he supposed, the deceased in a sound sleep, and lying in a composed and natural position. About fifteen minutes past eight A.M. the servant knocked at his door, and receiving no answer, went to his bed and shook him, but without rousing him. She found the bed clothes almost entirely covering his head, and immediately alarmed the inmates, when I was sent for, they supposing him to be in a fit. When I saw him first I found him in the following position:—He lay on his right side, the head rather bent on the chest; limbs flexed, the knees being up, the limbs were rigidly fixed in this position; in fact the whole body was as that of a person in tetanus; the jaws were firmly closed, and the tip of the tongue, which protruded, had been lacerated. A pocket handkerchief, rolled up, was pressed tightly over his mouth and nostrils by his hands, which were rigidly fixed in that position, the fingers being bent in segments of circles. The whole of the dependent surface of the body was deeply discoloured, of a purple colour, from the ordinary gravitation of the blood; the pupils were about the natural size; the body was almost cold; the rectum and bladder had been evacuated.

Sectio cadaveris.—11 A.M., June 24th.—The first circumstance noted, in making the integumentary incision, was *an exceedingly fluid state of the blood*, which was very *dark* in colour. The brain and membranes were healthy, the former perhaps not being of so firm a consistence, as natural, and slight congestion being evident in both; the sinuses at the base were largely distended with blood; the same state was also observed at the upper part of the spinal cord. The lungs were perfectly healthy in structure, but somewhat congested, and a frothy fluid exuded on pressure; they were not collapsed or but partially so. The heart appeared to be larger than usual, but this arose from the *excessive distention* of the right cavities with *very dark* fluid blood; the left cavities were almost empty; the structure was perfectly natural; valves, endo- and peri-cardium healthy. The *stomach* contained a quantity of dark reddish-brown matter, apparently the last meal which had undergone reduction in the stomach. The mucous membrane was moderately congested and vascular, but not more than probably occurs in healthy digestion; it was not at all softened. The liver, spleen, kidneys, intestines, and pelvic viscera, were perfectly healthy, but the venous system in each, was largely engorged with blood. There was not the slightest internal wound.

Observations.—The chief point of interest in this case was the cause of death; and to assist in discovering this, it will be necessary to note several collateral circumstances connected with the case.

1st. In a watch pocket just over deceased's head, was an empty half-ounce bottle, the cork being loose in the same pocket. Not the slightest smell could be detected arising from anything the bottle might have contained.

2nd. The pocket-handkerchief which covered the mouth was perfectly free from odour.

3rd. In a private drawer belonging to the deceased was found a one-ounce bottle, containing about five drachms of chloroform. Knowing the great volatility of chloroform, I performed an experiment with regard to this point; I took a small bottle, containing one drachm of chloroform, and having poured it on a pocket-handkerchief, I wrapped the latter up tolerably close, and allowed the bottle to remain open. In three hours I could not detect any smell from either which would justify me in stating that chloroform had been present.

The appearances presented by the *post-mortem* examination, were those of death by apnœa (asphyxia.) The question arises—How was this produced? Chloroform produces various effects, according to quantity, purity, duration, and manner of inhalation. Thus anæsthesia, general insensibility proceeding to profound coma, paralysis of voluntary, and afterwards (very probably) of involuntary motion, are its usual effects, according to the length of time administered. Convulsive action has been remarked in many instances. I have seen a case in which violent maniacal delirium resulted, lasting two or three hours, relieved by opium. In the case in question, the apnœa may have been the result of—1st, profound coma, from prolonged inhalation; 2nd, or, more immediate, from prevention of entrance of air into the lungs, by closure of the external orifices of respiration, by the hands and handkerchief, these effects being increased by convulsive action, which would also implicate the larynx and trachea; 3rd, or, from a combination of all these circumstances, as is most probable. Now, supposing the deceased to have inhaled chloroform, the following is my impression as to the course of events. He poured the usual quantity (say ½ drachm to 1 drachm) on his handkerchief, laid himself down, and (probably, although thoughtlessly) to increase its effects, pulled the bed-clothes over his head, the usual effects of chloroform took place, insensibility resulted, consequently he could not remove the handkerchief from his mouth on account of his peculiar position in bed.

The inhalation would thus proceed, evaporation of the chloroform being greatly prevented by the bed-clothes, at the same time the air being almost entirely excluded. The next effect would, most probably, be convulsive action, of a tonic character; this may in a great measure be inferred from the rigid condition of the muscles after death, which was far greater than the usual rigor mortis. The handkerchief would thus be pressed more closely by the hands against the mouth and nostrils, the rigidity affecting more especially the flexor muscles. Apnœa would be the result, and consequent death from—1st, the chloroform producing insensibility; 2nd, the passage of air to the lungs being prevented, or nearly so, by the continued inhalation, as well as by the external orifices of respiration being in a manner closed, and by the convulsive action implicating the glottis, together with the external respiratory muscles. All these causes would concur in

producing apnœa. And there can be little doubt, from the circumstances detailed, that chloroform was continuously inhaled for a long time, and produced its fatal effects from the peculiar concurring circumstances above mentioned. Had he inhaled it whilst sitting up in bed, the result would, most probably, not have proved fatal. The quantity inhaled it is impossible to state, but the quantity usually employed might produce death under such circumstances as those above mentioned.

Bank Street, Sheffield,
January 21, 1851.

REMARKS ON CASES IN PRIVATE PRATICE.

By W. C. COOKSEY, Esq., Worcester.

ON A NEW APPARATUS FOR CLUB-FOOT.

In the *Journal* of the 26th of June last, I directed attention to a method of treating talipes equinus by a simple apparatus, and I mentioned at the time that a modified splint on a similar principle, might be applied to other forms of the same affection, with equal advantage. I have since used the splint to which I refer in a case of equinus varus; I found that its effect in bringing the foot to the proper angle with the leg was as good as possible, but something more was necessary to uncurb and expand the contracted foot, and to give it as early as possible the power of being placed flat and firmly on the ground. I therefore had an apparatus made, of which the following sketch may convey an idea, and which has answered the end in view perfectly well:—

Fig. I.

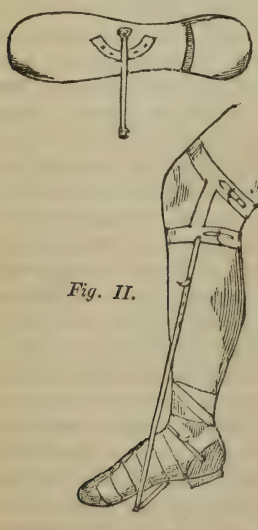

Fig. II.

It consists of a wooden sole somewhat larger than the bottom of the foot, (*Fig. I.*); to the under surface of this is attached a bar of steel about four inches in length, and moving loosely on a pivot in the plane of the sole; this bar may be placed at any angle with the long axis of the sole, and secured in its position by means of a stud on its upper surface, which enters the holes in a segment of brass let into the sole. At the free end of the bar is an eye holding a strap, which meets the buckle on the collar at the knee, *Fig. II.* Thus the pull may be made in any direction or to any extent. I do not know any case of deformity affecting the foot and ankle-joint, in which this splint may not be available, or in which, unless the case be beyond the reach of mechanical art, a cure may not be effected by its use, after the proper division of the tendons, it being always borne in mind, that while no class of cases may appear at first sight more hopeless than those in question, there are none which better repay a diligent, careful, and patient use of the remedial means which we possess for their relief.

In applying this apparatus, the foot should be first firmly bandaged down as flat as possible on the sole, and to prevent its moving aside when the strain commences, the heel should be surrounded by a piece of stiff leather, three quarters of an inch in depth, with a strap to buckle across the instep over the bandage. The sole and collar must be carefully padded, and the whole removed once a week, without which precautions the long-continued pressure may endanger the skin.

DEATH CAUSED RY THE IMPACTION OF A PIECE OF WALNUT IN THE LARYNX OF A CHILD.

On the 26th of October my attendance was requested upon a child who was thought to be dying; I was from home, as was also another medical man to whom the messenger applied. When I arrived at the house, the child had been dead half an hour. The parents told me it had been attacked while in perfect health, with sudden difficulty of breathing, threatening immediate suffocation; it apppeared in great distress; there was no cough, but a wheezing sound on each inspiration. The symptoms, as described, appeared to resemble those of sudden œdema of the parts around the glottis, but the manner of the attack, and the rapidly fatal termination of the same scarcely bore out this view. I passed my finger into the pharynx, expecting to find some foreign body pressing upon the glottis or otherwise impeding respiration; the throat, however, was clear, and the parts natural and healthy. I then requested leave to examine the body, which being granted, on the following day I cut down upon and removed the larynx and part of the trachea, when the difficulty was at once explained. A piece of the kernel of a walnut had passed through the rima glottidis, and was wedged within the cricoid cartilage, by the ring of which it was firmly embraced, so as to be with difficulty removed. The angular shape of the walnut, by allowing the passage of a small portion of air, accounted for the little patient having survived the accident an hour and a half. It was only six month's old. The case appears to me to suggest the question of—How far, under similar circumstances, mechanical interference would be justified? as, for instance, endeavouring to pass an elastic bougie through the rima glottidis before thinking of tracheotomy, with the view

of dislodging the body obstructing the passage of air, and of facilitating the natural efforts of the parts concerned in its expulsion through the rima.

ACUTE RHEUMATISM, WITH HYDROPERICARDIUM, AND DEATH, IN A CHILD THREE YEARS OLD.

In the afternoon of the 27th of October I was called to a child of nearly three years old. Upon examination I found the whole of the right lower extremity much and uniformly swollen; the shape of the joint being lost, and the skin tense and elastic; there was not uniform redness, but patches appeared at intervals, the size of a shilling, of a dusky red colour. Upon my attempting to move the limb the child cried out suddenly and violently, and every subsequent motion, however slight, appeared to cause excruciating pain. So far the symptoms were those of acute rheumatism. The skin was acting freely; tongue white and moist, papillæ elongated; bowels open; pulse 140, and somewhat feeble. I found the affected limb enveloped in a warm soft poultice, which was ordered to be continued. The child was placed in a warm bath, and Hydrarg. Chlor., gr. j.; Pulv. Doveri. gr. ij; Antim. Pot. Tart., gr. 1-6th; given every second hour. I told the parents that the heart would probably be affected, but did not think myself called upon to apply any special preventive measures in so early a stage of the disease, the child having been in perfect health two days before I saw it.

In the evening I saw the case again. She was lying quiet, the eyes closed. I felt the pulse, and found that she was sinking. She could be roused without difficulty, and replied clearly to questions; but some fatal influence was evidently at work, and the vital powers were failing. The pulse was fluttering, and could not be counted; the eyes were surrounded by a dark circle; the swelling and pain on moving the limb were not lessened. Fatal effusion was evidently going on somewhere; and though I ascribed the symptoms to affection of the heart, by metastasis from the limb, they were yet not defined enough, nor was there sufficient strength remaining, to justify any vigorous treatment by blistering or depletion. I ordered support to be administered, and Hydrarg. Chlor., gr. ½, alone to be given every half hour. The child died at six o'clock next morning, sixteen hours after my first visit.

On the following day I examined the body. The morbid appearances were confined to the heart and left lung; the pericardium was distended with clear straw-coloured serum, in which the heart floated; there was no vascularity, or roughening of the serous membrane, neither did the serum contain any flakes of lymph; the left lung was gorged, the lower and posterior portions extremely so; the organic structures were perfectly sound. The case, therefore, appeared to have been one of simple hydropericardium, produced by metastasis of rheumatic effusion from an extremity to an internal organ, without inflammatory action.

I should be glad to know if any of the readers of the *Journal* have met with cases such as I have just attempted to describe. Authorities speak of both the remarkable points which distinguished this case, viz., acute rheumatism in a child three years old, and passive hydropericardium without inflammation, as extremely rare. That the latter was not a *post-mortem* appearance was sufficiently clear from its amount, which completely distended the pericardium, and surrounded the heart with fluid.

Worcester, Nov. 26, 1850.

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

REPORTS OF CASES ADMITTED UNDER DR. DAVID NELSON.

Extracted from the Clinical Records,

BY W. J. MOORE, ESQ. M.R.C.S., AND L.A.C., RESIDENT MEDICAL OFFICER.

Case XVI.

Case of Charles Rowe, aged 30. *Temp. nervo-lymphatic. Affected with Phthisis, terminating in Recovery. Admitted as an out-patient March* 11*th.*

History.—This patient, nine months before, had caught a cold, which he neglected. Three months after he had consulted Dr. Morris, of Preston, who appeared from the prescriptions to have treated a bowel complaint with mercury and chalk, to have also stopped hæmoptysis by acetate of lead, and subsequently used paregoric and squills, in conjunction with blistering. Ever since he had used the lead he stated his bowels had been constipated.

Symptoms.—On examination he was greatly emaciated, and had pale sharp features; his tongue was speckled; he had very troublesome cough, and expectorated a thin ropy mucous; he had no sickness, but his bowels were very costive; he had profuse night sweats; there was dulness under percussion beneath the right clavicle, which was sunken, and on the same side, posteriorly, and also over the lower portion of the left lung; resonance elsewhere good; there was a good deal of sibilant wheezing throughout, which at first marked the bronchial respiration; pulse 104; respirations 38. He now weighed seven stone two pounds.

Diagnosis.—That there was tubercular deposit in the upper portion of the right lung and lower portion of the left.

Treatment.—This was commenced by an endeavour to excite the bowels, allay the cough and wheezing, stop the sweats, with counter-irritation, and the orders were:—Hab. Tinct. Opii Camph., Tinct. Hyoscy., Spt. Æth. Sulph. utrq., gtt. xx., ter die. Pil. Aloet. j., omni nocte. Acid. Sulph. Dil., gtt. xxx., horâ somni. Ol. Aselli c. Ferro, dr. j., ter die. Ap. Vesicat. Sterno.

23rd.—The cough was easier, and the wheezing was gone; the sweatings were slight; the bowels were regularly opened, and his appetite was somewhat improved; pulse 90; respirations 30. Cont. Med.

30th.—The cough was easy, and there had been no return of wheezing or sweating; the appetite was good, but the bowels were difficult to be moved; the resonance in the dull part in front seemed somewhat improved, but the right side posteriorly remained the same; pulse 104; respirations 26. Cont. Med.

April 7th.—There was little cough; the respiration was bronchial, and in other respects he was much the same as at last visit. Cont. Med.

18th.—The sounds on percussion were better, except under the right clavicle; he had no return of sweats, and the cough was as easy as before, but he complained of sore-throat, and of "feeling something in it after hawking;" he had just been walking, and the pulse was 112; respirations 30. He had gained one pound in weight. He continued the medicine, had two leeches applied to the throat, and used an inhalation of iodine and conium.

28th.—He was easier again in all respects; pulse 70; respirations 26. Cont. Med.

A few days after he caught a fresh cold, and was then visited at his own house by Dr. Nelson's Clinical Clerk, Mr. Banks, who supplies the following additional notes:—

"The patient had now caught cold, and felt too unwell to walk to the hospital. He complained of pain in the chest and right shoulder; his cough continued to harass him night and day, and prevented sleep; the expectoration was muco-purulent; the tongue was coated with a brownish fur; the bowels were very costive; the urine scanty, high coloured, and depositing a red sediment; his appetite was gone; his skin hot and dry, and night sweats had returned; there was bronchial respiration on the right side, but no great dulness under percussion, except behind and over the lower anterior part of the left lung; pulse 120; respirations 38. He was blistered again, took his opening pills and the ferruginated oil, with paregoric.

"May 11th.—The bowels were regular, and the tongue was clean; there was no sediment from the urine; the cough was less troublesome; he felt a degree stronger, and his appetite had returned; the night sweats continued; pulse 100; respirations 34. Cont. Med., et sumat. Acid. Sulph. Aromat., gtt. xxx., horâ somni.

"14th.—The sweatings had nearly ceased, and his cough was still easier; pulse 92; respirations 24. Cont. Med., et Ap. Ung. Ant. Pot. Tart. sterno.

"21st.—He was much the same as at the former visit, but felt he was improving in flesh and strength. On being weighed it was found he had gained ten pounds since the 18th of April, notwithstanding the late acute attack. Pulse 92; respirations 22. Cont. Med.

"29th.—His bowels were regular; his tongue clean; his cough easy, and his sweatings gone, but he felt weak and languid; pulse 84; respirations 24. Cont. Med. et Hab. Decoct. Cinchonæ, oz. ss.; Inf. Calumb., oz. ss.; Quininæ Sulph., gr. j., ter die.

"June 4th.—His appetite and sleep were good; his bowels regular, and urine clear; the cough had nearly ceased; he felt stronger altogether, and was much improved in appearance; pulse 84; respirations 24. Cont. Med.

"18th.—The cough had ceased to trouble him, and he had no pain; sleep continued good; he had no return of sweating, and there was no bronchial respiration in any unnatural position, except close to the right shoulder. He was now sufficiently strong to walk for an hour or two at a time without undue fatigue. He had gained in weight about six pounds more, making in all seventeen pounds since March 11th. Pulse 80; respirations 18. Cont. Med."

Mr. Banks again saw him from professional curiosity on the 21st of October, and furnishes another note as follows:—

"He has not taken any medicine since last June, but has been careful in avoiding cold, &c. He has no cough or nocturnal sweating. There is no appreciable dulness on percussion. His appetite and sleep are good, and he has no sense of weakness. The skin is moist, the bowels regular, and the urine plentiful and healthy. Pulse 75, respirations 18. Recommended to take the ferruginated oil occasionally, and to be careful as to diet, exercise, &c."

Observations.—This case affords good ground for satisfactory reflection, and fairly justifies the use of the word recovery, though that of cure is to be cautiously avoided, inasmuch as after any recovery the original diathesis will still remain. The diagnosis is based on a series of symptoms too palpable to admit of dispute. The previous hæmoptysis followed by the cough, the sweatings, the emaciation, and the dulness, with the exalted pulse and respiration, point but to one legitimate conclusion. On the other hand, the gradual departure of the cough and sweatings, the expectoration and dulness, with the diminution of frequency of the pulse and respiration, and the notable increase of weight just as irrisistibly prove an augmented capacity of chest, an absence of constitutional irritation, and a restoration of the nutritive powers. The simple facts of the pulse falling from 104 to 75, the respirations from 38 to 18, and the weight increasing seventeen pounds, speak more emphatically than any speculative comments as to less demonstrative symptoms. As remarked by Dr. Hughes Bennett, it is well to keep such cases in view in order to obtain tangible proof of the ulterior result, as in this instance.

BRISTOL ROYAL INFIRMARY.

SURGICAL CASES ADMITTED UNDER AUGUSTIN PRICHARD, ESQ., SURGEON TO THE INFIRMARY.

Case I.

Extirpation of the Globe of the Eye.

James Fleming, aged about 46, admitted September 22nd, 1850, was formerly a workman in some iron foundry in Monmouthshire, where he met with an accident, thirteen years ago. He states that a piece of iron

entered his left eye, and has never been extracted. He has lost his sight for many years: and the constantly recurring inflammation in the injured eye has kept up so much sympathetic irritation in the right that he has been for a long time disabled from gaining his livelihood by his own exertions. For nine months he has been suffering from constant pain and sleepless nights, and his general health has accordingly suffered. His eye is intensely red, and the lids swollen; and he continually complains that he feels the foreign body rolling about from one side of the eye to the other. He is also quite unable to use the right eye, from the great intolerance of light. The iris of the injured eye is tremulous.

He became at first a patient at the "Bristol Dispensary for the Cure of Complaints in the Eye," many months ago, when, after careful attention to the case, I refused to make any attempt to remove the foreign body which he fancied was still there. He returned after three or four months' absence with the same symptoms, but there was a small black point in the sclerotic immediately below the cornea. Thinking that this might be the iron presenting itself externally, I made a section upon it, but discovered that it was merely a point where the sclerotic had become thinned. A considerable quantity of fluid and brownish vitreous humour escaped, and the eye appeared partially collapsed for a few days, after which pain returned, and the only difference observable in his eye was, that the pupil was distorted and drawn downwards towards the opening which I made.

A second attempt to cause the eye to collapse was made some weeks afterwards, when he was admitted an in-patient at the Bristol Royal Infirmary. Upon this occasion I removed a considerable flap of the cornea, and passed in a curette, to endeavour to remove the lens, if it was still there. The vitreous humour escaped as before, but no lens was to be felt.

The symptoms still remained in all their severity, and as he was extremely anxious to have something more done for him, I proposed, as a last resource, the removal of the globe of the eye. This was agreed upon in consultation, and he willingly consented; and I performed the operation in the usual way on the 14th of October, the patient being under the influence of chloroform. There was but little hæmorrhage; and after applying a twisted suture to the wound in the external canthus he was removed from the operation room, still in an insensible state. He recovered his sensibility about half an hour after the operation, two drachms of chloroform having been used.

15th.—Has slept but little; feels no pain.

16th.—Has had no pain whatever since the operation. Removed the pin from the outer canthus, the wound being healed.

17th.—Is up and well; the right eye is becoming strong; there is a little sanious discharge from the left orbit.

23rd.—Went out quite well, his right eye being quite strong, and the sight good.

The following appearances were seen upon examining the eye that was removed:—

The globe of the eye of a natural shape; the muscles healthy as far as they were removed; the anterior chamber healthy. The wound made in the cornea in a previous operation has partially united through the medium of a rounded mass of dense white lymph. The pupil had regained its circular form. Ciliary body healthy in appearance. Upon exposing the posterior part of the eye, considerable changes were visible. The retina was sound, the lens had disappeared, and the capsule was collapsed, hard, and opaque, occupying the lower part of the eye, pressing against the ciliary processes. No foreign body was to be found. A thick and firm layer of fibrin separated the sclerotic and choroid throughout their entire extent, and upon the outer side of the globe of the eye there was a deep oval cavity as large as a dried horse bean, and of a very similar form, situated in the middle of the fibrinous exudation. This was, in all probability, the cavity of an abscess, although when I made the section through the eye, immediately after the operation, and before I carefully dissected it, I observed no escape of pus. Passing through this little space were two fine cords, one larger than the other; these were a ciliary nerve and artery, which having traversed the sclerotic were dragged out of their natural position, or elongated by the gradual separation of the surfaces of the choroid and sclerotic, and this appeared like two little pillars connecting the opposite walls of the little cavity. The choroid itself appeared healthy, and of its usual brown colour.

This case is interesting as being the first recorded instance, as far as I can discover, in which extirpation of the globe has been performed for a disease of the eye which is not malignant, and I should scarcely have proposed so severe an operation if it had not been possible to remove all suffering by means of chloroform. It is also most satisfactory as far as the result is concerned, for, from the changes that had occured in the eye, it is quite clear that no other means could have removed or cured the disease, and the freedom from pain which the patient enjoyed from the time of the operation was complete. The cause of the intense neuralgic pain which he suffered was, in all probability, the irritation of the ciliary nerve kept in a state of tension as I have described, and the existence of the lymph between the sclerotic and choroid with the abscess in the centre, was quite sufficient to account for the constantly inflamed condition of the eye. I should think that, with the aid of chloroform, a similar operation might be performed in many instances with advantage, in incurable inflammation of the interior of the eye, when the sight has been permanently lost, and when the sound eye is endangered, as it undoubtedly is, by the disease of the other.

Provincial Medical & Surgical Journal.

WEDNESDAY, FEBRUARY 5, 1851.

THE letter of Mr. CARTWRIGHT, inserted in our last number, demands, and has received, our careful consideration. We can assure that gentleman that it was on no light grounds that we were induced to come to the resolution to which he alludes; but it is due to the Worcester Council to relieve them from all responsibility in connexion with that determination, the question never having been in any way before them. It appears to us that Mr. CARTWRIGHT labours under a serious mistake in considering the Council of the Association and the *Journal* as absolutely identical. It is quite true, as he says, "that they cannot, or ought not, according to common sense, to differ in sentiments," but at the same time, it does not follow that all that is inserted in the *Journal* as the opinions of the Editors, should be considered as having had the sanction of the Council; for it would be exceedingly inconvenient, as far as the Council is concerned, that every article should be submitted to them, nor do we suppose that any Editor would be able to make such an arrangement.

The Association, as a body, stands pledged to certain principles, which were embodied in the memorial presented to Sir GEORGE GREY by Sir CHARLES HASTINGS, during the last session of Parliament. From those sentiments, which had been previously carefully collected from the District Branches, there can be no retreat until they are rescinded by the same authority by which they were then enunciated, and we are confident the Worcester Council will lose no opportunity of enforcing them upon Her Majesty's Government, upon all proper occasions, and without any consideration for the time or trouble expended.

We have thus endeavoured to dispel Mr. CARTWRIGHT'S fears as to the lukewarmness of the Worcester Council in the cause of Medical Reform, which we again repeat, are utterly groundless. But we are called upon by our esteemed associate to reconsider the reasons which induced us to come to the determination of avoiding for the present the discussion of medical politics, and in order to do this we will state more at length what those reasons are. In the first place, we have for some time past been privately urged by many influential members to avoid the subject altogether, as leading to angry feelings, when harmony would otherwise prevail. In the second place, we were told that the subject was worn thread-bare, and had become "stale, flat, and unprofitable;" and, in the third place, we were advised that no readers like to have sentiments propounded in opposition to their own, especially where their vital interests are at stake; and that this is still more galling when the writer is elected by the body composed of the readers themselves. These arguments, we ourselves think, are by no means conclusive, but still they are entitled to our consideration, and for some time past we have acted upon them, and should have continued to do so without any open announcement. Latterly, however, we have received so many urgent requests to make allusion to the new Bill proposed to be brought into Parliament by Mr. WYLD, that we must either have been guilty of want of courtesy to those gentlemen and others who think with them, or have given our reasons for a non-compliance with their wishes, and hence arose the necessity for publishing the leading article of January 8th.

It must be borne in mind that at the last anniversary meeting, a Committee was appointed to consider the propriety of altering the form of the Society's publications; that Committee has as yet made no report, and therefore any alteration of plan can only be temporary and inconclusive; but we considered, that with a strong difference of opinion in many of our associates, and with a doubt existing in our own minds, it was better to avoid the subject altogether, as was the custom in the time of our lamented predecessor, than to run the risk of doing irreparable mischief to a cause, which we yield to none in our anxiety to support.

With the vast number which it is our object to please, in conducting this *Journal*, it is out of the question to hope that there should be uniformity of opinion on any subject. Nor do we expect, when we are told on indisputable authority, that "no one can serve *two* masters," to be able to serve nearly 2000 without offending some among them; it is not, therefore, on that ground that we thought it desirable to avoid the discussion, but solely from a fear of doing an injury to the Association. We have always, in conducting this department of the *Journal*, en-

deavoured to try all questions by the rules laid down by the general or special meetings, and when the proposed alterations in medical polity have not been in accordance with those rules, we have thought the discrepancy a fair subject for animadversion; but if it is generally thought that the Editorial department of the *Journal* should not be made a vehicle for the discussion of such matters, we shall be happy to bow to the decision of the majority; and if, on the contrary, the generality of our readers should think we have been of service to the profession—to which we are proud of belonging—by any arguments which we have put before them, and should wish for a continuance of a similar plan of proceeding, we shall have great pleasure in doing all in our power to aid in effecting the object which we are sure all have at heart, though there may be a difference of opinion as to the best mode of arriving at it. We willingly give credit to all, and especially to our friend Mr. CARTWRIGHT, for this sincere desire to increase the well-being of the profession, and we claim a like indulgence for ourselves.

Reviews.

Address to a Medical Student. Second Edition, pp. 167. Oxford: John Henry Parker, 1850

IT affords us the most unqualified pleasure to have to notice this small unpretending volume. Unlike most of the manuals and addresses to students in medicine, which are so frequently occupied either with abstruse scientific discussions which beginners do not understand, or with impracticable rules for the government of the understanding, or for the subdivisions of the day, that would lead one to fancy that it was a medical machine of some kind that the writer was talking of, instead of a poor pilgrim on his journey to a better land—

("Hope lifted, doubt-depressed,
Seeing in part,
Tried, troubled, tempted")

the writers of this volume state that they had before them the object of presenting the student in medicine with a plain and simple view of the profession upon which he is entering, its difficulties and its dangers no less than its pleasures and advantages. They also, and chiefly, wished to remind him by *whose* aid alone he can be enabled to keep himself unhurt by the temptations which will assail him; and to *whose* service all his powers, both of body and mind, are to be dedicated. At the same time, in order to render the work more practically useful, they wished to show how the principles recommended should be carried out and acted upon in the various scenes in which he necessarily is placed.

With these objects in view the essay is divided into different chapters, relating to the choice of a profession; the hospital; the dissecting room; the lecture room; daily life; the examination. One or two of the points noticed in the chapter on the choice of a profession, we would on the present occasion desire to bring before our younger readers, in the hope that they may thus be induced profitably to invest a half-crown in the purchase of the essay itself.

"*The choice of the Medical profession and of the Motives which ought to lead to it.*—Johnson has described the medical profession to be 'a melancholy attendance on misery, a mean submission to peevishness, and a continual interruption to rest and pleasure.' A desire either for comfort, independence, or pleasure, therefore, would not be the motive to lead any one to the choice of this profession. Certainly he would find none of these to be its rewards—nay, worldly ambition can scarce be gratified by the most assiduous and successful cultivation of the science of medicine. 'The lawyer, the soldier, the sailor—nay, the clergyman, may each climb almost to the topmost round of ambitions's ladder, while the physicians—in this country at least—can reach no higher rank in society than a title, which even worldly men think hardly worth the striving for."

Again, to take a higher view of the common motives which lead to, and are urged to, the choice of our profession,—*the desire to benefit our fellow-men*, and to spend a life of usefulness or even of *benevolence* to mankind. Yet this motive should not suffice to induce any Chistian man to make choice of the medical profession. "The gift of healing is one of the noblest gifts of God's holy spirit; and still it is very possible to spend a life in the exercise of this gift, and which at the same time may be a life of ungodliness." We can only recal too many painful instances of this truth: of men so immersed in the practice, and in the benevolent practice too, of their profession, as entirely to neglect the concerns of their own soul. This great truth, so neglected we fear, by our profession, has been thus beautifully stated by Dr. Arnold, in one of his Rugby sermons. May his words be a timely warning to the young in these times of ceaseless busy strife, which are rendering life one hard weary combat.

"We may be thankful to God when he makes our training for eternity consist in doing great and useful actions, in bringing forth much fruit; but we each of us are doing our business as thoroughly, are answering as completely the purposes for which *we* are sent into this world, if we are laid for years of our life upon a bed of sickness, incapable of any further action than that of glorifying God and perfecting our own souls by patient love. The welfare of nations, the improvement of the world on a large scale are (if I may use such an expression) God's object and God's business; thankful and happy may we be, when, by the particular call of His Providence, he chooses us to be His honoured instruments in accomplishing His work. But yet we should rejoice with trembling, lest while thus engaged in what I have ventured to call God's peculiar work, we may chance to neglect our own; while practising or ministering to, or enlightening or governing others, we ourselves should be cast away. It is not, therefore, true, that our great business or object in the world is to do all the good we can it; our great business and object is to do God's will, and so to be changed through his spirit into His image, that we may be fit to live with him for ever. His will is declared to us by the course of his providence, putting us into different situations of life, where different duties are required of us; but these duties are duties because they are His will; and if performed without reference to Him;—if done for worldly objects only, be they ever so extensive and beneficial;—if done solely to improve mankind and not to do the will of our heavenly Father, then our great business in life is left undone, and the most helpless sufferer, who has been bedridden for years, has spent life better and better answered the end for which he was born than we."

Thus a desire for honours ease, luxury, or a love of a benevolent useful life, are not motives which should suffice to authorise a choice of our profession. "What, then," says the writer, (p. 28,) "you will be inclined to ask, what ought to be my motives for choosing this profession? If I may not have wealth and honour for my object, nor ease nor comfort, nor even the delight of doing good to my neighbour, what ought to be my aim in life?—what other and better motive can I have?" "Nay, not so; think once again; for there is in truth one other motive still behind, and that is *the wish to serve and please God.*"

Yet, with this high motive, unless there be also considerable energy and perseverance of character, with ability above the average, and with all the means of getting *daily bread* for some few years independent of the profession, the writer has well pointed out (p. 29) the unsuitableness of choosing the medical profession.

But if neither these nor any other obstacle seems to block up the path at the very outset of the journey through life, and in a manner to force the choice of another profession, then *many reasons do exist to him whose object is to serve and glorify God, why the medical profession should be his choice.* These, in the concluding portion of the chapter under notice, the writer proceeds thus to enumerate, and with this rather long extract we fear we must bring our notice of this essay to a close.

"In the first place, then, as our Lord is the Great Physician of souls, who healeth all our spiritual sicknesses, so is the healer of bodily diseases one of the most evident types of him; and great should be the comfort which the practitioner derives from the reflection that the Son of God Himself, while on earth, condescended to assume this character, which is indeed one of the most interesting in which He is represented to us in the Gospels. In the second place, remember that the whole business of the physician is to do good to his fellow-men, and that in exerting his talents to the utmost with this object he cannot do amiss. * * * * * * * * Again the very fact I have mentioned, viz., that wealth seldom falls to the lot of the physicians, and the common worldly honours of rank and title scarcely ever, though to worldly men a reason for rejecting the medical profession, may to many a young Christian, who has escaped from the snares of ambition, be one of his chief motives for choosing it. For mere earthly objects no longer move his desires; it is God's honour and glory that he has in view and not his own; 'he has no property, since he is but a steward of the Lord; he has no honour or shame of his own, after the manner of the world, this being his only honour, if God be glorified, and his only shame if He be dishonoured by him;' while all his aim is so (by God's grace,) to pass through this painful life that he may one day hear from his Saviour's lips those blessed words, (how much more precious than the proudest earthly title!) 'Well done, thou good and faithful servant; thou hast been faithful over a few things, I will make thee ruler over many things; enter thou into the joy of thy Lord. * * * * * Another reason for choosing the medical profession may arise from the fact of the physician's being thrown constantly into close personal contact with his poorer brethren. How important, and even necessary, this is for the spiritual perfection of most men need not here be told, especially as I shall have occasion to say a few words on this subject in another place; I would now only remind you, with George Herbert, that

> 'Man is God's image, but a *poor* man is
> Christ's stamp to boot.'—

Then again, consider, that as the practice of the medical profession is useful beyond all others, so also is the study of it almost beyond all others noble and elevating; for in what part of the field of creation are there to be found more and plainer proofs of the goodness and power and wisdom of God? And as both the moral and religious parts of the physician's nature are daily brought into action, so too, is the intellectual; for in what human branch of study is there more room for acuteness and talent, or in what is there greater need of clear apprehension, sound judgment, and accurate reasoning?

"Is it not good that, while so many things within us and around us are daily tempting us to put away the thoughts of death, and to enjoy the present hour, we should have some friendly monitor to force us to remember our latter end, and to think of the joys and sorrows, not of this world, but of eternity? In this respect how highly favoured is the physician in having such repeated calls vouchsafed to him; but at the same time how much will it increase his condemnation if he be like the deaf adder, and stop his ears against the voice of God, and neglect his gracious warnings.

"Yet once more, forasmuch as God's true servant feels that he is a 'stranger and pilgrim on the earth,' and 'desireth a better country, that is, a heavenly;' that 'here he hath no continuing city, but seeketh one to come,' and is journeying towards 'the heavenly Jerusalem;' that, 'while he is at home in the body, he is absent from the Lord:' he will not think it good to pass his days and nights as if he were already in his home, and were to remain here for ever, and so had only to live a life of self-enjoyment. * * *

"To one who enters into this feeling how welcome will be the toil, the carefulness, the want of ease, the broken rest of the doctor's life; because all this will serve to prevent his setting his affections on things below, and will make him look forward the more steadily (though not impatiently) to the perfect rest of heaven, where 'there shall be no more death, neither sorrow, nor crying, neither shall there be any more pain, for the former things are passed away,' and in their stead there shall be only rest and peace, and the fulness of joy for ever. * * * * * *

"And now, to conclude this chapter:—If these reasons, or others such as these, shall (after earnest and devout prayer for the direction and guidance of God's holy spirit,) lead you to conclude that the medical profession is that in which you can best serve and glorify him, and best work out your own salvation; then how blessed will be your choice, blessed both for time and for eternity! How blessed an encouragement will it be to you, while a student, to think that all your studies are under His direction, and that, as it is for His service that you are being trained up, so it is His voice that speaks to you in your daily work; that it is He who sometimes throws doubts and difficulties in your way, to exercise your faith, and then that it is He who gives you wisdom to solve them, in order to call forth your love and gratitude! How blessed a comfort will it be when you have entered upon the duties and responsibilities that belong to a practitioner, to feel that you are doing God's work, and not your own, and that you are the chosen instrument in His hand for diffusing health and strength around you; to think of him as guiding you, watching over you, sometimes allowing your best efforts to fail, to teach you to be humble, and then, again, correcting your errors, and suggesting, by some new or unobserved symptom, the *proper plan of treatment*. How blessed an assurance, in either station, is the thought that you have prayed to be guided in your choice by Him, and that He has guided you. How blessed is the consciousness that in every act of your professional life, you may say with a holy confidence:—'To this end was I born, and for this cause came I into the world!'"

Notice of an Unpublished Manuscript of Harvey. By G. S. Paget, M.D., Fellow of Caius College Cambridge.

The only value of the MS., which Dr. Paget has rescued from oblivion, is its fictitious one as an archæological curiosity. It appears to have been a syllabus of a course of lectures, very badly written, and interspersed with quaint jocularities which ill accord with our preconceived notions of the "Immortal Harvey." However, it is probable, judging from the following comparison of the brain nerves to military commanders, soldiers, and magistrates, that the great discoverer of the circulation never intended his notes to go beyond his own portfolio, little dreaming of the indefatigability with which anything old and useless would be hunted up in the nineteenth century. At page 18 we find—

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

Case of fatty degeneration of the heart, fatal by rupture of the right ventricle.

Dr. Johnson, of Shrewsbury, presented through Dr. Fletcher, the following case:—

Ann Weston, aged 72, was admitted into the Salop Infirmary under the care of Mr. Arrowsmith, January 5th, 1850. She was very thin, pallid, and unhealthy in appearance, complained of great debility, coldness of the extremities, and general chilliness of the whole body. On admission she had a chronic ulcer in each leg. There was always a great want of action about the ulcers. One of these had, however, at length healed, the other did so afterwards, but it again broke out. There was no suspicion excited that she laboured under any organic disease of the heart.

May 11th.—About two hours after dinner she had first risen from her bed, and after sitting at the fire dressing herself, she was seen to walk away towards her bed, upon which she fell down, uttering a faint scream, and died almost immediately.

Sectio-cadaveris.—The body exsanguine; the extremities wasted; the abdomen and chest plump for her age. The viscera of the chest and abdomen *appeared healthy*, except that the pericardium had a

peculiar dark colour, which on being laid open was found to arise from a large clot of dark venous blood. The heart was found so completely covered with fat, that it seemed as if the whole organ was made up entirely of adipose tissue. There was an ecchymosed space at that part of the right ventricle which is nearest to the apex, through which space were two openings, large enough to admit a probe, and leading into the right ventricle; this was evidently the part from whence the large quantity of extravasated venous blood had proceeded. The walls of the right ventricle were two-thirds made up of *fat*. The proper muscular substance of the ventricle was pale, soft, flabby, easily torn, and had lost the characteristics of muscular structure as seen with the naked eye, and when examined with the microscope. In some portions, from the internal walls of the right ventricle, it was observed—1st, that the natural fibrous structure was destroyed, so that anything like a muscular fibre could hardly be seen; it was still more difficult to discover any trace of the transverse *striæ;* 2nd, innumerable oil globules were seen mixed up with the muscular tissue; 3rd, the morbid specimen left abundant traces of *oil* upon the glass slide.

I have thought it worth while to preserve a record of this case, because Professor Hasse, in his "Pathological Anatomy,"* says that there are but four instances on record of *rupture of a fatty heart,*—a very unlooked for circumstance, when we consider the softened and disorganized state of the muscular substance of the heart.

Our case corresponds very exactly with the account given of the disease by Hasse. We have a mixture of the two forms of the disease. The adipose deposit having commenced in the sub-serous tissue, had extended to the proper muscular texture of the heart. *Advanced age* appears to exert a material influence over this affection. Thus out of thirteen cases mentioned in the work already quoted, *six* were like our case, above *seventy years* of age.

For the above details of the history and morbid appearances I am indebted to Mr. J. R. Humphreys, the House-Surgeon of the Salop Infirmary.

Aneurism of the left middle cerebral artery.

Dr. Fletcher brought forward a specimen of aneurism of the left middle cerebral artery, communicating with a cavity in the anterior lobe of the brain.

The patient, aged 33, a painter, was brought into the hospital at a quarter past nine o'clock on the 23rd of May, 1850, in a condition of fainting. He could not stand, but assisted in taking off his coat. He had been admitted into the hospital under Dr. Fletcher's care on the 19th of February, suffering from painter's colic, and his hands permanently dropped. He went on well until the 28th, when a severe attack of gout in his feet came on. He left the hospital well with the exception of the dropped hands. It ought here to be stated that he squinted with both eyes, from permanent opacities of the cornea, the result of severe inflammation about ten years since. His senses were perfect, and he was quite intelligent.

After leaving the hospital his health was good, and some of his friends remarked that they never saw him better than on the morning of the 23rd. At four o'clock in the afternoon he was standing at a window observing a tremendous thunderstorm; immediately after a flash of lightening, he declared it had struck him. An hour and a half afterwards he was found foaming at the mouth, prostrate on his back, and perfectly insensible. He soon was able to walk between two men, but at first dragged his right leg behind him, and he was able to say "yes," which he did to every question put to him. He looked like a man recovering from a fainting or epileptic fit. At one o'clock convulsions came on, with stertorous breathing, countenance remained pale, he sunk into a profound coma, and died a little after two, being eight hours since he was first found insensible, and about nine and a half since he complained of the electric stroke.

Post-mortem thirty hours after death.—Head: Extravasation of blood upon the surface of the left hemisphere of the brain, and at the base, chiefly anteriorly, and much more on the left than on the right side. A small aneurism of the upper side of the middle cerebral artery was found, which communicated with a cavity in the anterior lobe of the brain, and extended backwards over the striated body, capable of containing a fair-sized walnut; it contained a clot of blood, besides a considerable quantity of fluid blood, and appeared to have formed a part of the boundary of the aneurism, and it appeared that the rupture of this aneurism produced the extravasation of blood. The substance of the brain was healthy, except that the left striated body was much darker in colour, and more vascular than the right. The urine in the bladder was found albuminous, and the kidneys in the first stage of Bright's disease.

Dr. Fletcher said that this man must have been the subject of the aneurism of the middle cerebral artery of the brain, and of the extension of it into the anterior lobe of the brain for some time, as it is well known that a chronic disease of the brain is borne by the patient without ill effect, comparatively with the same extent of disease taking place suddenly, and therefore it might with justice be inferred, that the cavity in the anterior lobe of the brain had taken some time to form. It must have existed at the time he was in the hospital, and yet there was no symptom to indicate its presence.

Tubercular Deposit in the Kidneys.

Mr. Thursfield, of Broseley, presented the following particulars of the case to the Society, through Dr. Fletcher:—

William Bird, a collier, aged 37, was seized seven years ago, with sudden and violent pain in the region of the bladder, which lasted for some days. A year afterwards he came under my care, and had occasional hæmorrhage from the bladder, always preceded by violent pain and a constant discharge of muco-purulent matter mixed with the urine, and very highly offensive.

* Sydenham Edition, p. 170.

On examining the body, the liver was found rather enlarged, but quite healthy, as were the stomach, pancreas, spleen, and mesentery; there were several old and firm bands between the peritoneal coat lining the abdominal parietes, and the bowels and omentum, but no tubercle was traceable. The chest was not examined, but he had never had any symptom of disease of the lungs. The bladder was very small and much thickened, the mucous membrane being covered with a coating of creamy-looking substance at the anterior portion of the fundus, it strongly adhered to the peritoneum, near the symphisis pubis; on attempting to separate it, the coats tore like a piece of brown paper. The prostate was not in the slightest degree diseased; the kidneys were filled with tubercles, the right being at least four times the size of the left.

Extreme Disease of the Aorta and of its Valves; Enlargement of the Heart.

Dr. JOHNSON, of Shrewsbury, presented the following particulars through Dr. FLETCHER :—

Dr. Johnson had but few notes of this case, as the patient came into the infirmary under one of his colleagues, in a moribund state. His age was 46, by trade a wheelwright, and he had not been an intemperate man. A peculiar and strong rasping sound was heard over the cardiac region, and even at the bend of the right elbow. The aorta was exceedingly diseased, being one sheet of irregular bony plates, and atheromatous deposit; the aortic valves were rigid with osseous deposit. The heart much enlarged.

Pulmonary Apoplexy.

Dr. FLETCHER brought before the Society the lungs of a man affected to an enormous extent with apoplexy.

Edward Upton, aged 45, a labourer, a temperate man, was admitted into the General Hospital, April 26th, 1850. About eighteen or nineteen years since he had frequent bleeding from piles. The last two years the piles have troubled him very little. For the last five months he has been ailing, low, and weak, with about the lower part of the bowels, short breath, emaciation, and at length he became so short of breath that he could not lie down. When admitted he had great irregularity of the heart's action, without any valvular sound or intensity of action. His legs slightly œdematous, and the urine acid and moderately albuminous.

May 3rd.—Much prostrated; countenance indicative of great mischief; skin dry; extremities cold; he has a catching pain about the left side of the chest, at the outer and upper part; a loose cough, and the expectoration deeply tinged with blood, amounting in quantity to about half a pint in twenty-four hours; respiration quick, with some effort, and slight motion of the ribs; the respiration is found rough, dry, and bronchial, and the percussion clear; pulse thready; the ribs over the heart raised, forming a distinct elevation; the action of the heart so extremely irregular that it is impossible to distinguish the different sounds, and frequently there is much action of the heart and several beats, to which no corresponding impulse of the pulse is felt at the wrist.

7th.—Weaker; cough more frequent; hæmoptysis increased; heart's action still more irregular, and the pulse also more variable, with less correspondence between it and the beats of the heart; chest becoming generally duller than natural on percussion, especially behind.

Gradually getting worse in every respect until the 19th, when he died, after having become quite jaundiced.

Sectio-cadaveris.—Body much emaciated, and generally of a jaundiced tint. *Head:* Brain healthy. *Chest:* Both lungs, with the exception of the upper half of the upper lobe of the left, were generally and equally in extent, in an apoplectic state, of a dark-red colour, gorged with blood, non-crepitant, and sinking in water; heart dilated generally, and the tricuspid valve so large as to allow with ease the four fingers to be passed into it. *Abdomen:* Stomach and intestines healthy; spleen and pancreas healthy; liver nutmeg; kidneys connected by their upper extremities, so as together to represent a horseshoe, slightly granular, and a deposit of fibrin existed in one part, as if the remains of an extravasation of blood. Ureters and bladder healthy.

There was in this case no great dilatation of the veins of the neck, as might have been expected from the tricuspid being dilated to such an extent; and Dr. Fletcher had thought that the mitral was more in fault than was found to be the case.

Foreign Department.

On Anæsthetic Agents.—By M. ARAN.*

The next question which M. Aran seeks to solve is the *effect of the employment of anæsthetic agents upon the health of the mother and infant.* On this point he observes :—

"As regards the influence of anæsthetic agents on the mother and infant, the early results experienced by MM. Simpson and Dubois are quite confirmed. Ætherization of the mother has no perceptible effect on the child, or if it does influence it, it is solely by a slight acceleration of pulse. Dr. Simpson has given the results of 150 labours in which chloroform was used, of these one infant only was born dead, and that was putrid; and a second, the subject of cyanosis, died a few days after birth. Drs. Duncan and Norris also declare that when infants have been still-born, the chloroform had nothing to do with it. And again, Dr. Murphy states, that in 540 labours, in which æther or chloroform was used, there was not one still-birth."

"In reference to the influence of anæsthetics on the mother, it may be affirmed freely, that there is no ground for apprehension. Of 1519 females thus treated by Dr. Simpson, no accident happened that could be rationally attributed to these agents. Dr.

* Continued from page 47.

Murphy did not meet with a single instance of death in 540 natural labours under chloroform; not one in 37 forceps cases; only one in 27 cases of turning; and 2 only in 20 cases of perforation. Drs. Duncan and Norris have contrasted the results of 93 labours under chloroform with 50 conducted in the ordinary manner. These results are entirely in favour of anæsthesia. They state that the females delivered under chloroform are exempt from the lassitude of ordinary labours; they are cheerful when the effect has passed off, and they frequently fall into a natural sleep. "Not only," says Dr. Simpson, "do these women escape pain, but the knowledge of the fact has a favourable influence on the convalescence, which is shorter, and more free from complications than in the generality of cases." It does not appear, moreover, that there is a greater frequency of other accidents which may endanger the life of the woman. Three of these have been chiefly feared, namely, rupture of the perineum, uterine hæmorrhages, and convulsions, but experience has proved the futility of such apprehensions. It appears, therefore, on the whole, that the maternal economy so far from being injured by the use of anæsthetics, is, on the contrary, benefitted by them, both in the act of accouchement and in its consequences."

"We now arrive on a question of paramount importance. *What are the indications and counter-indications for the employment of anæsthesia in midwifery?* Is the comparative harmlessness of anæsthetic agents a sufficient reason for their use in midwifery? Dr. Simpson, and with him many of the physicians of the north, decide in the affirmative, considering that the pains which occur in the last stage of labour should be regarded in the same light as those which attend severe operations; so regarding them, it is impossible to refuse to the suffering woman the solace which is accorded to the subject of the surgeon's knife. Of the religious objections we need scarcely speak, they are less urged here than in England. But there are other objections, based upon physiological doctrines, which have considerable weight with many practitioners; among these M. Bouisson considers the pains of the lying-in woman as destined to insure her safety, since they inform the attendant of the stage and actual progress of the labour. But the same may be said of pain in surgical operations, and on this ground we ought equally to object to anæsthesia in surgery. In expressing our own opinions, we should say that in a natural labour, with pains of average intensity, anæsthetic agents may, with good reason, be dispensed with. But the case is different in præternatural labour, in which manipulations are necessary, which are in themselves the occasion of additional suffering. Whenever, for some reason, the pains are unusually severe, as from a faulty presentation, rigidity of the soft parts, narrowness of the brim, &c., all hesitation should vanish, and we should avail ourselves of anæsthetic agents, as powerful auxiliaries to the ordinary measures."

"In obstetrical operations there is evidently as much reason to defend the patient from the effects of nervous shock as in surgery; wherefore the employment of anæsthesia in such cases has not been discountenanced, even by those who are opposed to it in ordinary labours. Dr. Montgomery has recognised the utility of the practice in instrumental delivery, in turning, and in artificial extractions of the placenta. Certain accoucheurs have expressed doubts as to the propriety of inducing anæsthesia in forceps cases, and in cases requiring perforation, from the fact that some degree of sensibility is required, as a warning against injuring of the soft parts. But this objection is more apparent than real. When the rules for the application of the forceps are strictly observed an anæsthesia does not increase the risk. It may be mentioned that in the case of obstetrical operations a greater degree of insensibility is required than in ordinary labour."

M. Aran here recapitulates the different methods for exhibiting chloroform which have been recommended in obstetrical practice, pointing out principally the rules laid down by Dr. Simpson and Mr. Snow; after which he proceeds to report "on the *medical use of anæsthetic* agents:"—"It is not in surgical operations alone that pain is experienced; it is the sad appanage of a great number of diseases, and in some forms the essential morbid element. It is against pain that the power of anæsthetic agents has been chiefly invoked in medicine; but they have also been used to remove spasm and other abnormal muscular action. In tetanus the spasms have been undoubtedly relieved, but they have unfortunately recurred after a brief interval, and in some cases they have been actually increased by the inhalation.

"This uncertainty in the action of anasthesia in medical practice, together with the deaths which have followed in certain cases, prevent my entertaining a sanguine view of the therapeutical employment of these agents. Without denying the services which they have rendered, they are too powerful to be brought into general use, more especially as oftentimes the same effects may be produced with less risk by their local application. This mode of using them is, however, still in its infancy; and we must wait for its further development before we venture upon any decided opinion respecting its merits."

PROCEEDINGS OF THE FRENCH ACADEMIES.

ACADEMIE DE MEDECINE.

The Academy has been recently occupied with the very important question of the effect of the administration of *ergot of rye* on *infant* mortality. The Prefect of the Department of the Seine, struck with the large proportion of still-births, and having ascertained from the registrars that in many of these cases the ergot had been given, was moved by the coincidence, and demanded an expression of opinion by this Academy respecting the propriety of using this drug, especially by the midwives. On this demand M. Danyav presented a report.

The reporter commenced by stating that, given in proper doses, and with precaution of constantly watch-

ing the fœtal circulation, by the aid of auscultation, the ergot is perfectly safe in a great majority of instances. But this harmlessness is not constant; and the prolonged exhibition of the drug for an hour or two may be attended with disastrous results. As regards the mother, he stated that in repeated small doses its only effect was diminution of the frequency of the pulse; and in larger doses it may generally be given without risk, though under peculiar circumstances it may give rise to rupture of the uterus, or vesico-vaginal fistula. As a remedy for *post-partum* hæmorrhage, the ergot is invaluable; and its action is the more favourable the earlier it is given. Speaking of the reported abortive powers of ergot, M. Danyav denies that it is capable of exciting uterine action, *per se*, in the early periods of pregnancy.

In conclusion, M. Danyav drew the following deductions:—1. Ergot when given injudiciously may indubitably cause the death of the infant, and may cause injury to the mother. 2. In the presant state of the law it is not possible to lay down any positive rules for the guidance of midwives in the exhibition of this medicine.

The Academy next entered upon the consideration of two reports, both having reference to phthisis pulmonalis; one by M. Grizolle, "On *the Inhalation of Carbonic Acid Gas* in Phthisis, and *on a New Sign of Latent Tubercles*;" another by M. Wanner, "On the *Etiology of Tuberculization.*" The memoir reported on by M. Grizolle is by a Dr. Goin, who endeavours to prove that the inhalations of carbonic acid for three hours per diem is very salutary, and induces absorption of tubercles. The reporter, we need hardly say, thinks differently.

M. Landouzy spoke of amaurosis as a frequent accompaniment of albuminuria.

M. Chartrue introduced the inhalation of iodine in phthisis. He apparently is not aware that this have been for some time a favourite remedy "among the consumption curable" doctors of this country.

Other useful papers were read, of which we may particularize one by M. Bernier, "On the *Treatment of Intermittents by Arsenic;*" one by M. Maisonneuve, "On *the Resection of the Entire Upper Jaw*;" and one by M. Hutin, "On the Necessity of Extracting Spicula in Gunshot Wounds."

General Retrospect.

PATHOLOGY AND PRACTICAL MEDICINE.

How to Choose a Microscope.

The following remarks on this subject, by Dr. Hughes Bennett, may be useful to some of our readers:—

"A microscope may be divided into its mechanical and its optical parts. Of numerous models which have been invented the following is most useful:—The body consists of a telescope tube eight inches in length, held by a split tube three inches long. It may be elevated and depressed by a corkscrew movement for the coarse adjustment. It is attached to a cross pillar and bar, at the lower end of which is the fine adjustment. The stage is three inches broad, two and a half deep, with a circular diaphragm below it. This form of instrument possesses the very essential elements of steadiness, facility of adjustment, and portability.

Dr. Bennett also figures a pocket microscope devised by Dr. Gruby, which is of great utility. It is contained in a case the size of an ordinary snuff-box, and possesses all the conveniences of the larger instruments, with various lenses, micrometer, &c. Dr. Bennett endeavours to disabuse the reader of the idea that the magnifying power of an instrument is proportionate to its size.—*Edinburgh Monthly Journal*, Dec. 1850.

On the Pathological Expression of the Dumb-Bell Crystals in the Urine.

By Dr. Fricke and Dr. Wilson.

In the *American Journal of Medical Sciences*, July, 1850, Dr. Fricke calls in question the generally received opinion, first promulgated by Dr. Golding Bird, that the dumb bell-crystal is indicative of the presence of oxalate of lime in the urine. Dr. Fricke says, that he has for many reasons doubted the correctness of this view, and that they are, in reality, but disentegrated crystals of uric acid.

[The opinion that the dumb-bell is not characteristic of oxalate of lime, as is supposed by Dr. Golding Bird, but is a modification in the crystallization of urea, is confirmed by some observations by Dr. Morris Wilson, from which he has elicited the following interesting facts:—

Firstly. That dumb-bell crystals are very frequently developed as the result of certain modifications of uric acid.

Secondly. That it is not to the salts of urine alone that this formation is confined, they are frequently met with in solutions which have no organic origin, and in a variety of salts.

The author continues:—]

I should perhaps premise, that although nature seems to accomplish her ends without effort or excess, and sometimes most unexpectedly, it is occasionally very difficult, in prosecuting experiments, to arrive at satisfactory results. I am led, however, to the conclusion, that the form of the dumb-bell crystal depends upon a specific but independent force, developed under certain determinate circumstances, consentaneously with that of homogeneous attraction or aggregation.

I have observed, that when spicular crystals commence forming upon a centre, after stretching some little distance in a straight line, they begin to branch and spread outwards; and that as this lateral force is more or less vigorous, that of extension is arrested, and the tuft of spiculæ spreading from the central point, assumes the flattened globular shape, in a proportionately complete degree, and the same action taking place at both ends of the primary crystal, constitutes the dumb-bell form.

It appears to me that this effect arises purely from the agency of electricity; and that, as an arranging power, it is quite separate and distinct from that of aggregation, and depends for its influence upon the repulsive force manifested towards each other by similarly electrified bodies.

But it is not my intention to enter into the very interesting subject of crystallization generally, many new phenomena of which actual examination by the microscope has taught me, but to confine myself to the form and construction of the dumb-bells of uric acid. Uric acid and oxalate of lime occur very frequently together in the same deposit, and from their combined presence very different forms of dumb-bell crystals are found together; it is, therefore, of the first importance to separate each salt carefully, before proceeding to subject it to experiment.

While analyzing some urine of high specific gravity, and in which there was a copious precipitate of uric acid, I added a solution of caustic potash in sufficient quantity to dissolve the deposit. The urine thus treated was twice filtered; a light flocculent cloud of uric acid, in combination with potash, made its appearence in a short time, and gradually subsided to the bottom of the vessel. The supernatant fluid being decanted off, hydrochloric acid, in great excess, was poured suddenly upon the sediment, which after a rest of about a quarter of an hour, was found converted into a thin layer of opaque dark-brown uric acid dumb-bells. These differed in the most marked degree from the dumb-bell of oxalic origin by their great insolubility in water. But the experiment is open to the doubt that an oxalate might have gained entrance.

I then separated some highly crystallized uric acid from the urine in which it was deposited, and washed it thoroughly with large quantities of warm water; it was then dissolved in pure caustic potash, and filtered through paper. On adding strong hydrochloric acid in excess to this solution, dumb-bell crystals were deposited, some being of very perfect form, others not so.

Some pure lithic acid was dissolved in concentrated sulphuric acid; to this solution two-thirds of water were added, and there occurred an instantaneous precipitation of imperfect dumb-bells. To show the difficulties of this kind of demonstration, and the changes likely to result from varied circumstances, a small quantity of this concentrated sulphuric solution being dropped into a large bulk of water, the resulting deposit consisted of thin broad plates, the two edges of which, in the longitudinal direction of the spiculæ, were considerably thickened, forming ridges; but these plates, when rolled over on their thin edges for examination, also presented a dumb-bell form, though from their narrowness it was impossible to retain them on the edge.

The dumb-bells to which I wish to call attention and give a description are those obtained in the deposit caused by the addition of hydrochloric acid to the potash solution. My reason for so doing is because I have observed the same forms as a natural deposit among uric acid; and these, although of such a remarkable form, have, I believe, until the present time, been left undescribed.

They consist of a thin translucent plate, of an oval or rhomboid form, having a slightly elevated ridge running along their middle in the direction of the long diameter, and from near the extremities of which extend two compact kidney-shaped crests of thin spicular crystals, their long diameter being across the plane of the translucent plate. A transverse section of one of the kidney-shaped crests would present an oval outline.

From the way in which the weight is arranged—namely, in the centre of the crests—the crystal has, while under the microscope, a tendency to float with the edge of the thin plate turned towards the eye of the observer. Circumstances, however, occasionally seem to dispose the face of the thin plate to be directed upwards, and then, without a close and careful examination, by rolling the crystals over, their dumb-bell shapes might escape the eye of the microscopist, and seem to represent only rhomboid plates of uric acid.—*Lancet*, Oct., 1850.

Yeast in the Treatment of Scarlet Fever.

Mr. Bennett, of Gateshead, states that during an epidemic of malignant scarlatina, which came under his notice in 1847, he found no plan equal to that of giving fresh yeast. He says that after ammonia, the mineral acids, chlorate of potass, and even nitrate of silver to the fauces, have failed, he has found one or two tablespoonfuls of fresh yeast, given frequently, to be rapidly efficacious. [There is nothing new in this.—Ed. P.J.] —*Medical Gazette*, Jan. 10th.

SURGERY.

Rupture of the Cicatrix of a Burn.

Dr. Bagot introduced to the notice of the Surgical Society of Ireland a little boy whose arm had been greatly contracted after a burn. A day or two after the healing of the wound the boy fell while running in the street, and in the act of falling his arm was caught by some obstacle, so that the cicatrix was suddenly torn, with great effusion of blood. The wound was again allowed to heal without the intervention of surgery; but the cicatrix did not contract in the slightest degree, and the child has recovered the perfect use of his arm.—*Dublin Medical Press*, Jan. 8, 1851.

Excision of the Head of the Femur.

At a recent meeting of the Medical Society of London a paper on this important operation was read by Mr. Haynes Walton.

After remarking upon the diversity of opinion concerning the propriety of this operation, the author said, the leading question was, at what stage of the disease the operation should be performed. There were two considerations to be taken into account—1, the local; 2, the constitutional. With reference to the first, he thought, when the discharge was excessive, thin, dark, and of bad odour: in respect to the second, when there

was much hectic fever. If, on examination, disease of the internal organs could not be discovered, especially of the lungs, the operation should take place. There was a question whether disease would not sooner or later come on in these from the effects of the local disorder upon the constitution, if the local mischief were not removed.

The author did not consider the acetabulum to be so often diseased in morbus coxæ as the head of the femur; and that, when diseased, it had greater power of reparation.

He believed non-dislocation of the head of the femur to be diagnostic of soundness of the acetabulum; and that, by exploratory incision, or by passing the finger through a sinus, the state of the acetabulum might often be discovered. If there were no disease in the acetabulum, the operation would most probably be successful, although cases had turned out well where there had been disease in that portion of the joint. Out of fourteen cases, twelve of which had been collected from different sources—the other two having occurred in his own practice—six had proved fatal: one had died from renal disease, another from hæmorrhage from the profunda vein, another from diarrhœa: the cause of death in the other three was not given.

The operation was in reality much less severe than it appeared to be. The wasted state of the parts facilitated the operation, while the loss of blood was remarkably small.

The author did not advocate removal of the trochanter as well as the head of the bone. The long interrupted splint was the best apparatus to apply after the operation. —*Lancet.*

Ununited Fracture treated by Electricity.

By Dr. Lente.

N. R., aged 25, admitted with simple fracture of the left femur, about the middle, with shortening an inch. Various plans were tried to ensure union, but these failing, some through the perverseness of the patient, the limb was eventually secured in a double inclined plane, so arranged that the integument over the seat of fracture was exposed. Electro-galvanism was applied three times a week, together with acupuncture, the needle being passed to the periosteum on each side. This treatment was continued near four months, when consolidation appeared to be taking place, and in six weeks more the union was firm.

The second case was that of a female, aged 35, with ununited fracture of both bones of the left leg. The limb was applied in the fracture-box, and as there was considerable inflammation, cooling lotions were applied until the swelling had subsided. Partial union ensued, but as it did not become firm, electricity was employed, as in the former case, and with similar success.

After narrating a third case, Dr. Lente remarks that he considers electricity to be a valuable agent in such cases, but it requires to be combined with acupuncture. It appears, he observes, to have but little effect when the poles of the battery are merely applied to the soft parts, as the current does not then appear to reach the bones.—*New York Journal*, November, 1850.

Tetanus from Laying Open an Inflamed Bursa.

The following case affords a severe lesson as to the impropriety of opening the enlarged bursæ of the knee to which housemaids are subject:—

The patient was of the age of 23, of a sanguineous temperament and hasty disposition. She was admitted into Guy's Hospital under Mr. Hilton, for an inflamed bursa, accompanied by febrile disturbance. The swelling was incised, and a small quantity of pus escaped. Poultices were applied, but the wound did not assume a healthy action, and it became necessary to extend the incision, to allow of the escape of some sloughy matter. After this she improved, until the sixteenth day, when about five P.M. she began to complain of stiffness of the neck and jaws, which she attributed to cold. Next day the stiffness had extended, and the pulse had risen to 110. She took calomel and opium, and aconitine was rubbed into the spine, in the proportion of one grain to the ounce of spermaceti, half a drachm being used at each friction. In spite of this tetanic symptoms became more and more pronounced, and she died in a paroxysm on the seventh day.

It was observed that the aconitine was of great service in relieving pain, but had no control over the progress of the disease.—*Lancet*, Nov. 30, 1850.

MIDWIFERY.

Rupture of the Uterus Twice in the same Subject; the last fatal.—By Dr. Hartt.

Dr. H. was sent for in May, 1846, to a female who had been in labour three days. She was exhausted, with a pulse of 108. On examination he found the shoulder presented; that there was a laceration of the neck of the uterus, through which the head, and the head only, of the child had passed. He immediately seized the feet, and delivered with little difficulty. He gave the patient an anodyne, and waited beside her four hours, expecting that she would die. At the end of that time, however, she seemed to be better, and he began to cherish some faint hopes of her recovery. She did recover; and about eighteen months afterwards she was delivered of a living child upon a raft in the river, without assistance of any kind.

On the 13th October, 1849, he received a summons to visit her again on a similar occasion. When he arrived she had been in labour four days. She was very weak; pulse 118 and feeble; breathing very hurried. The account gfven by the attendant was, that the hand presented, that her pains were severe, and that twenty-four hours after they began a snap was distinctly heard by her friends around her couch; that the hand receded, and from that moment the labour had been suspended. Suspecting the true state of the case, Dr. H. instantly examined, and found a large opening precisely in the seat of the former rupture, and passing on his hand he felt the child in the cavity of the abdomen.

The patient was so far exhausted that he was unwilling to interfere. He described both to herself and to her friends her alarming position, and stated that, owing to the length of time which had elapsed since the accident occurred, he feared that no operation could prove successful. They all, however, expressed great anxiety that an effort should be made, and at their repeated and earnest solicitations he proceeded to turn and deliver her *via naturales*. The operation was performed with great gentleness, and particular care was taken to avoid unnecessary injury to the bowels. He remained with the patient several hours, administering anodynes and restoratives, but in vain. She gradually sank and died thirty-six hours after delivery. The interesting feature in the case of this patient was, her complete recovery from the first rupture, and the perfect union of the parts, a union sufficient to sustain the violence of the unassisted delivery of a large and vigorous child.—*New York Journal of Medicine*, Nov., 1850.

On Superfœtation.—By Dr. Alexander Henry.

Dr. Henry has published a lengthened essay in which he classifies cases of superfœtation as follows :—

1. Cases in which a dead twin has been retained in the uterus.

2. Cases in which the children have been born, either—

(*a*) Both at the same time, but of different degrees of development, the smaller fœtus being either alive, or recently dead; or

(*b*) Where the less perfect fœtus has been retained until it became mature.

3. Cases in which children of different colours have been born.

4. Cases in which a double uterus has been proved to exist.

5. Cases occurring during extra-uterine gestation.

Each class is illustrated by example.—*London Journal of Medicine*, September, 1849.

TOXICOLOGY.

Poisoning with Cantharides.—By M. Arreat.

The *post-mortem* appearances in a case of poisoning by cantharides are thus minutely detailed by the author.

The cavity of the mouth was covered almost entirely with thick white mucus, symptomatic of violent inflammation of the digestive tube. When removed with the handle of a scalpel, there appeared two considerable aphthous ulcerations on the back of the tongue and on the inner surface of the lower lip. The tonsils were both deeply ulcerated, indeed almost destroyed, and covered with copious thick yellow pus. The œsophagus presented unequivocal traces of severe inflammation throughout its whole course. The small intestines presented brown and reddish discolouration, indicative of inflammation. The liver exhibited a yellow discolouration on its duodenal surface. The bladder was of a brownish colour; this organ was indurated, contracted, and greatly thickened; its internal surface was completely covered with black fungoid patches, consisting of extravasations of blood in its altered structure. The cavities of the kidneys presented similar changes.

The small intestines contained no trace of the powder of cantharides, but particles of these were found in considerable numbers on various parts of the surface of the mucous membrane of the stomach, which exhibited abundant traces of inflammatory action, and in some parts was in a gangrenous state.

The rectum appeared as if an immense blister covered its muscular coat, filled with pus. Such an extent of disorganization M. Arreat had never before witnessed; and it was a source of regret that it was impossible so to preserve it that it might have been exhibited to others.

The fæces contained in the intestines were submitted to the action of alcohol, and a very large number of the particles of powdered flies were found therein.

The poison in this case had been administered certainly twelve or fifteen days (perhaps more than a month) before death. It appeared that a dose of at least two grammes (= 30 grs. Eng.) had been administered the day before death occured.

The symptoms appear to have been—obstinate costiveness, fearful colics, and a sensation of burning in the throat and rectum.

It was proved that the cantharides had been administered by the widow of the deceased.—*Journal de Chimie Médicale*, Nov., 1850, and *Medical Gazette*.

DEATH OF DR. HAVILAND,

Regius Professor of Physic in the University of Cambridge.

This event took place on the 8th. Dr. Haviland had for several years suffered under slight paralysis, consequent on a severe attack of fever caught in his attendance upon a patient, and had been in indifferent health during the last three or four months. On the evening of the 7th he was seized with apoplexy, and survived only a few hours.

He was a member of St. John's College; graduated as B.A. in 1807, being 12th wrangler; was subsequently made a Fellow of his college, took the M.A. Degree, and proceeded in Physic. In 1814, on the death of Sir Busick Harwood, he was elected Professor of Anatomy; and in 1817, vacating the Professorship of Anatomy, he succeeded Sir Isaac Pennington as Regius Professor of Physic. He was for twenty-two years Physician to Addenbrooke's Hospital, and had the chief practice as Physician in this town and neighbourhood. The shock which his constitution had received from the attack of fever in 1838 induced him to retire from practice, and he resigned his appointment at the Hospital in 1839. He retained the Professorship, but was obliged to avail himself of the assistance of Dr. Bond, who at various times delivered the lectures and performed the other active duties of the office.

Dr. Haviland was an excellent practical Physician; a quick, clever man, yet discreet, and possessed of sound judgment. His attention was directed less to the niceties

of diagnosis than to the minutiæ of treatment, in which he particularly excelled, being most fertile in his resources, and ever ready to impart information on those details of general management which, though highly important, are too often neglected by the educated practitioner. His manner to the patient and to the friends was so kind and winning that he gained their affection in no less degree than he acquired their confidence; indeed, he was universally esteemed and beloved. By the medical men of the town and county, one and all, he was regarded as a friend, almost as a father, to whom they could apply in their difficulties, and on whose kind interest and willing assistance they might implicitly rely. Enviable and highly honourable was his position in this respect; nothing could more truly attest the uprightness of his character, and the benevolence of his disposition, than the sincere respect and regard entertained for him by the whole body of his professional brethren. Of a sensitive temperament himself, he was very careful over the reputation of another, and always showed his anxiety to maintain inviolate that good feeling which should ever exist between the patient and the ordinary medical attendant. He was lively and unreserved in his demeanour, and had the art of placing his inferiors on an equality with himself, at the same time that he maintained, with an easy courtesy, the dignity of his position. Those only who have had occasion to seek his counsel, and they are not a few, can tell with what readiness he entered into their plans, with what frankness and judgment he tendered his advice. Endowed with an ample fortune, he was a munificent contributor to the charities of the town, and was ever ready with his purse and his presence to aid in relieving the necessities of the poor, and in promoting the cause of education and religion.

The professorial chairs of medicine in the Universities of Oxford and Cambridge are positions of more importance than is generally supposed by the world at large. The spirit emanating from them, though comparatively silent in its operation, is wide in its influence. They are the sources from which the leading members in the highest grade of the profession commonly receive their first instruction in the principles of the science; and the occupants of those chairs are the representatives of the profession in the two great seats of learning—the connectors, as it were, of medicine with the other branches of philosophy. To perform the difficult and and responsible duties of such a position, Dr. Haviland was qualified in an eminent degree; and during the six and thirty years in which it was his privilege to act as Professor he did good service to the University and to the medical profession. His great earnestness, his high character, his sound judgment, and his thorough knowledge of the academic system necessarily gave him much influence with the governing bodies of the University, as well as with the governing bodies of the profession in other parts of the kingdom. This influence he turned to good account: it has been mainly owing to his instrumentality that the faculty of medicine has been retained at all as an integral part of the University, in accomplishing which he had to contend with much lukewarmness within the body, and many attacks from without: and it is entirely owing to him that the medical school has attained its present efficiency; indeed, it may almost be said to have been founded under his auspices. As Professor of Anatomy, Dr. Haviland was the first to give a regular course of lectures on human anatomy in Cambridge; and as Regius Professor of Physic, he was the first to give lectures on Pathology and the practice of Physic. Before his time the proceedings in Physic were merely nominal, a few questions put *vivâ voce* constituting the only examination for the degree of Bachelor or Doctor of Medicine; at his suggestion and by his efforts a lengthened and systematic course of study has been required, rigid examinations have been instituted, and lectures on various branches of medicine and the collateral sciences have been regularly given in the medical school of the University.

Dr. Haviland was, moreover, a good classical scholar, and was remarkable for the elegant style in which he conducted the keeping acts and conferred the degrees, all this being done in Latin. He did not contribute much to medical literature, his only publications consisting of a Synopsis of his Course of Lectures on Anatomy, and "Some Observations concerning the Fever which prevailed in Cambridge during the Spring of 1815;" in the "Medical Transactions of the College of Physicians," Vol. 5.

Correspondence.

ON QUICK CHILDBIRTH, AS CONNECTED WITH CRIMINAL COURTS OF LAW.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—Those gentlemen who have been called upon to give evidence in courts of justice, on cases of suspected infanticide, and submitted to severe cross-examinations, will fully appreciate any fact, however trifling, which can strengthen their opinion upon a subject which has been involved in much doubt, as to the possibility of a female in good health and sound mind being delivered of a full grown child without her cognition; and having perused the interesting and valuable communication in your journal of the eighth of January, by Mr. King, of Bath, I think it a good opportunity to give the history of a case which has recently occurred in my own practice, being the only one I have met with during a series of twenty years' experience; and I hope that the importance of the subject will be a sufficient apology for its introduction to your journal.

Having been engaged to attend a lady, aged 34, in her first labour, I was hastily summoned to her house early in the morning, but on arriving there I was informed that the child was born a few minutes previously to the messenger leaving her, and that the infant was dead.

On making inquiries, I found that my patient thinking that she had a desire to use the night chair, attempted to make use of it, and there voided what she supposed to be the liquor amnii, and sat there some time afterwards, feeling much indisposed; but on getting into bed she saw, to her great astonishment, the child lying in the vessel quite dead. She declared most positively that she had experienced no pain, and was quite uncon-

scious of the exact state of her position. I weighed the child and found it to be six pounds and three quarters, and full grown, the mother having completed her full time of reckoning.

Now, as this lady and her husband had expressed great anxiety respecting the birth of the child, and every usual preparation had been made for its reception, there cannot be any reasonable doubt of her integrity in this matter, as there could be no possible object in concealing the birth. Had she been a single woman, I fear that a very different conclusion would have been drawn.

I have the honour to be, Sir,

Your very obedient Servant,

JOHN GREGSON HARRISON, M.D.,

Member of the Royal College of Surgeons of England, and Fellow of the Royal College of Physicians, Edinburgh.

Piccadilly, Manchester, January 21, 1851.

ANALYSIS OF THE MEDICAL DIRECTORY, WITH REMARKS ON MEDICAL REFORM

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—I made the enclosed analysis of the different qualifications enumerated in the provincial part of the "Medical Directory" of 1848, and it was inserted in the *Medical Times* of that year. I have seen several statements of the number and qualifications of medical practitioners in the different journals, but as they appear to be mere guesses, some of them very wide of the mark, you will probably allow its insertion in the next *Journal*. I have looked over the Directory for this year, but it does not appear to be as carefully edited as that of 1848, which may be owing to the dislike many practitioners have of being at the trouble of returning their qualifications every year. The changes which take place in the medical profession are not so numerous but that a biennial or triennial issue would answer its wants, and pay the publishers better. At all events the analysis of the Directory of 1848 will be a near approximation to the number of the profession of this year; those commencing their arduous duties as medical practitioners and the deaths being supposed to be about equal.

It appears to me that we are paying, in the discussion on Medical Reform, which at present is agitating the profession, too great attention to the shadow, and allowing the substance to vanish from our sight. Here we have fifteen hundred unlicensed practitioners feathering their nests and lining their pockets—"men who have a great deal of assumption and impudence, but blessed with little real knowledge, and that little generally of a very dangerous description"—whilst we are quarrelling about our titles, if I may so call a number of cabalistic letters with which we adorn our names, the meaning of which the public know nothing about and care less. The gentleman with his three tails considers it beneath his dignity to meet one with two, the one with two says, "Never mind, my two tails are as good as his three, I can cure you as well without him." But still this rebuff does not teach the gentleman with two tails meekness; he looks with contempt on the man with one tail, which perhaps may be as good for attaining the desired goal as the whole number put together.

Besides these fifteen hundred self-licensed practitioners, we have the druggists, quacks of every description, as herb-doctors, worm-doctors, water-doctors homœopathic *fraction*-doctors, bone-setters, old women-doctors, &c., besides the ministers of religion, from the highest in the Church to the Latter-Day Saints, to rob us of our just dues.

Do the public gain anything by this strife? They gain in obtaining the useful and faithful services of the medical man for a mere gratuity, and they may gain by lowering his status in society; but this gain is woefully and fearfully balanced by the mischief that has been previously done by quackery.

The coming session of Parliament would put an end to most of these evils if the profession would be moderately unanimous, but it will be again allowed to pass without anything being done to remedy the existing evils. Your correspondent of the 16th instant objects to the establishment of a third College. So do I; but on different grounds. He thinks that a third College would lower the status of the profession, but forgets that there exists at present a third institution, which has the sole power of granting a legal license to practise, and has used that power solely to raise the standard of the medical profession. He at least would be a gainer by the arrangement, for he would then be legally entitled to practise a branch of the profession for which he has passed no examination. If he is dependent on his profession this is the branch by which he must obtain the means of living; and he cannot avoid acknowledging that he has fifty cases of medicine for one of surgery; whilst he must feel lowered in his own estimation, knowing that his examiners have said that even in this small branch of his business he has only had an examination to treat the minor exigencies.

I object to a third College, as being totally unnecessary, and as tending to create disunion and discord, whilst there are two institutions existing capable of meeting all the wants of the profession; but these institutions have refused to do so, and if they still persist in their refusal what other resource is there left? The Apothecaries' Society have honourably offered to give up their privileges to the two institutions if they are willing to undertake the responsibility of the examinations, or, on their refusing, to a third institution with fuller powers and privileges than they at present possess; but they rightly say that they will neither sacrifice the interests of their members nor of the public till they are fully assured that those interests will be protected.

Why cannot the two institutions accept these powers, and obtain an act to that effect, which act must be prospective, not retrospective, and liberal in its provisions, extending its sanctioning powers equally to the gentlemen with one, two, or a dozen qualifications. The general practitioners might rank as licentiates, and the fellowship might be reserved for those who had an extended course of education, and as an honorary degree for those members who had been eminently useful to the profession.

I am afraid, Sir, that it is vain to hope that the

present session will not be allowed to pass without the adjustment of the difficulties agitating the profession, but if a little more gentlemanly feeling existed, harmony would begin to prevail, and the matter would soon be brought to a satisfactory and final close.

I am, Sir, your obedient servant,

L.A.C.

Analysis of the "Provincial Medical Directory."

In practice before 1815, many being members of the College of Surgeons, surgeons in the army or navy, or in the possession of other qualifications	613
Licentiates of the Society of Apothecaries, many being in the possession of Scotch or other qualifications, in addition to their certificate	1004
Fellows and Members of the College of Surgeons, many being in possession of other qualifications, but not having the certificate of the Apothecaries	1072
Members of the College of Surgeons, and Licentiates of the Society of Apothecaries, some of them being in the possession of other qualifications	3634
Members of the College of Physicians, or of the Universities of London, Oxford, or Cambridge	141
Members of the University of Edinburgh, some of them possessing other qualifications, but no diploma or license from any English Institution	334
Licentiates of the College of Surgeons, Edinburgh	110
Members of the University of Glasgow	52
Members of the Faculty of Physicians and Surgeons, Glasgow	26
Members of the University of Aberdeen, one practising in 1815	4
Members of the University of St. Andrews, one having been an army-surgeon, and another practising in 1815	5
Practitioners in possession of Irish qualifications	23
Practitioners in possession of foreign qualifications only	12
Practitioners in the qualified list, but no qualification annexed	25
Total qualified	7055
Unlicensed practitioners ...	1488
Total	8543

Medical Intelligence.

CREWKERNE AND YEOVIL MEDICAL ASSOCIATION.

At a general meeting of medical gentlemen held at Crewkerne, December 4th, 1850, William Tomkins, M.D., in the chair, it was proposed by Dr. Sydenham,—"That a Medical Association be formed in the neighbourhood, to be called the 'Crewkerne and Yeovil District Medical Association,' and that it commence its operations January 1st, 1851."

Proposed by Joseph Wills, Esq.,—"That the object of this Association be to promote unanimity and friendly communication among the members of the medical profession, and to advance its interests by the diffusion of information and the suppression of illegal practice."

Proposed by F. A. Hansard, Esq.,—"That this Society consist of a President, (to be annually chosen), Honorary Secretary, and ordinary members, any number of whom, being not less than three, shall form a committee for general or special purposes, to act when summoned by the Honorary Secretary."

Proposed by G. F. Wills, Esq.,—"That stamped periodicals, viz., the *Lancet*, *Medical Gazette*, and *Medical Times*, be circulated among the members, until the first general meeting shall determine whether a book society for the circulation of standard works shall be established."

Proposed by John Webber, Esq.,—"That an annual subscription of ten shillings be paid in advance by each member."

Proposed by G. S. Jolliffe, Esq.,—"That two general meetings be annually held, in April and September, alternately at Yeovil and Crewkerne, or at any other place which may be determined by the Committee."

Proposed by Joseph Wills, Esq.,—"That Dr. Tomkins be President for the first year."

Proposed by F. A. Hansard, Esq.,—"That Mr. G. F. Wills be the Honorary Secretary."

Proposed by H. Norris, Esq.,—"That the President, Honorary Secretary, Mr. Hansard, Mr. G. S. Jolliffe, Mr. H. Norris, and Dr. Sydenham form a Committee for the purpose of framing bye-laws, &c."

Proposed by G. F. Wills, Esq.,—"That this meeting are persuaded that much good may be derived from this Association, and hereby request the approval and cordial co-operation of all the medical practitioners in this neighbourhood, in their endeavour to support the dignity of their profession, both in public and in private, to correct abuses, and more especially to take active measures for the suppression of all unqualified practitioners."

Proposed by E. Bowdage, Esq.,—"That this meeting be adjourned to the 17th inst,, at 5 o'clock, P.M., to the house of Mr. G. F. Wills, Crewkerne, for the purpose of approving bye-laws and enrolling members."

All which resolutions were carried unanimously.

WM. TOMKINS, Chairman.

Proposed by Hugh Norris, Esq., and seconded by Joseph Wills, Esq., and carried *nem con.*,—"That the thanks of this meeting be given to Dr. Tomkins for his kindness in presiding in so efficient a manner.

G. F. WILLS, Honorary Secretary.

Crewkerne, December 6, 1850.

BIRKENHEAD COUNTY COURT.

MACDOUGAL *v.* MARTIN.—On Friday last a case was tried before J. W. Harden, Esq., involving points of material importance to the Medical Profession as well

as to the public. The plaintiff was Mr. Macdougal, lately house-surgeon to the Liverpool workhouse and fever hospital, but now of the infirmary and hospital of Birkenhead, and Mr. Thomas Martin, pilot of boat No. 10, the defendant. The court was crowded during the trial, which lasted nearly the whole of the day. Mr. Thorburne, barrister, conducted the plaintiff's case. Mr. Pemberton appeared for the defendant. The action was brought to enforce payment of a surgeon's bill arising out of attendance, &c., on the defendant's wife. It was proved that the deceased woman had laboured under a complication of afflictions. The patient had been attended by the plaintiff during her illness, and, aware of the danger she was in, had called in Mr. Dixon and Dr. Bickersteth, of Liverpool, for consultation. These gentlemen did all that their united skill and experience could devise, but it appeared that the mother of the deceased was dissatisfied, and dismissed the plaintiff and Mr. Dixon, after which she called in another surgeon who attended her till her death, which took place in three or four days. The claim was resisted on the ground that deceased had not been properly attended to. The plaintiff was also called upon to produce his diploma. Mr. Thorburne denounced the defence as more than vexatious. He objected to any man being called upon to produce his diploma, contending that it of itself was no evidence, and could not be judiciously noticed, as it might have been stolen, or lent, or procured through the personation of another party undergoing examination before the college granting the certificate. A man's oath that he was duly qualified was evidence, but not the mere possession of a diploma. The handwriting of the examiners and the seal would require to be proved; also the identity of the person purporting to have received it. Mr. Pemberton contended for the production of the document, but the judge ruled that it was not evidence, and that the burden of disproof that a plaintiff had not a diploma, lay upon the defendant. Considerable interest was manifested during the investigation, which was heightened by the repeated "scenes" which took place between the counsel—every inch of ground being disputed on matters of law and evidence. Mr. Dixon and Dr. Bickersteth had certified their approval of the treatment, but their documents to that effect were not received. Subsequently Mr. Dixon came into court, and gave his evidence at great length. After hearing Mr. Thorburne's reply, his Honour said the case was so important that he should take time for consideration, and reserve judgment till next court day.

MORTALITY IN PUBLIC INSTITUTIONS OF LONDON.

In the week ending Jan. 25, 88 persons have died in Workhouses—44 males and 44 females; in Military and Naval Asylums, 4 males; in General Hospitals, 46—21 males and 25 females; in Hospitals for Special Diseases, 10—6 males and 4 females; in Lying-in-Hospitals, none; in Lunatic Asylums, 1 male; in Military and Naval Hospitals, 1 male; in Prisons, none. Total in public institutions, 150—77 males and 73 females.

DEATH OF R. THORPE, ESQ., MANCHESTER,

This eminent surgeon expired on Tuesday, Jan. 21, at his residence in Piccadilly, Manchester. The deceased was in his 64th year. He was known, not only in Manchester, but throughout the kingdom, as one of the most clever anatomists and operating surgeons the three kingdoms contained. Having passed through the usual course of instruction in London, and the ordeal of examinations, he subsequently returned to Manchester, and commenced the practice of his profession. He became connected with the Manchester Royal Infirmary in 1812, by his election on the 2nd of April in that year, and resigned in 1849, but was immediately elected one of the consulting surgeons to the institution, and held that honourable position at his death. He was also a member of the Provincial Medical and Surgical Association. In private life Mr. Thorpe was distinguished by the benevolence of his character, and by the unostentatious manner in which he distributed his ample means among those whom he believed to be requiring and deserving of aid.

THE LATE ROBERT LISTON, ESQ.

A pension of £100 per annum on the Queen's Civil List, has been conferred on Mrs. Liston, the widow of the late Robert Liston, Esq., the eminent surgeon, whose sudden demise was so generally lamented as a loss to the country and the profession which he adorned.

THE BLACK FEVER.

It is reported that the village of Baldon, four or five miles from Oxford, which principally belongs to Queen's College, is now infected with a most malignant typhus fever, running into the old black fever. The cottages are miserable in the extreme, and greatly overcrowded.—*Medical Times.*

USE OF ANÆSTHETIC AGENTS IN ANCIENT CHINA.

Stanislas Julian has found, in examining the Chinese books in the National Library at Paris, the proof that the Chinese have been long acquainted with the use of anæsthetic agents during surgical operations. The extract which he gives is from a book published about the commencement of the sixteenth century, in fifty vols. quarto, and entitled "Kow-Kin-i-tong," "General account of Ancient and Modern Medicine," and refers to the practice of a celebrated physician, Ho-a-tho, who flourished between the years 220 and 230 of our era. It states, when about to perform certain painful operations, "he gave the patient a preparation of hemp" (hachich), and that at the end of a few moments "he became as insensible as if he had been drunk or deprived of life." After a certain number of days the patient was cured, without having experienced the slightest pain during the operation. In a subsequent notice he also adds, that the same physician used the hydropathic system as a cure for certain diseases, among others chronic rheumatism.—*Edin. Philosophical Journal.*

THE CENSUS FOR 1851.

Members of the medical profession are to state the university, college, or hall, of which they are graduates, fellows, are licentiates; also whether they practise as physicians, surgeons, or general practitioners, or not practising. Professors, teachers, public writers, authors, and scientific men, to state the particular branch of science or literature which they teach or pursue.

LIVERPOOL MEDICO-ETHICAL SOCIETY

The Annual General Meeting took place on Tuesday, the 21st of January last. The report of the Council was unanimously adopted, and ordered to be printed for distribution among the members. Dr. Formby was re-elected president. Mr. Blackburn was re-elected a vice-president. Sir Arnold Knight was elected a vice-president. Mr. Jones was re-elected treasurer. Mr. Harricks was re-elected honorary secretary.

LEITH HOSPITAL.

The annual meeting of the subscribers to this establishment, which comprises the Leith Dispensary, the Casualty Hospital, and a new Epidemic Fever Hospital, (for the founding of which the late Mr. Stewart left £1000,) was held lately in one of the large fever wards of the institution. The report stated, that the contract price for building the hospital was £1878, exclusive of external fittings and the expense of enclosing the grounds. The precise cost has not yet been ascertained. The office of House-Surgeon being vacant, it was proposed that the salary be £60 a-year instead of £40. In the dispensary department, medical aid has been afforded to 2099 patients, 1000 of whom had been visited at home by the house-surgeon, and many more by the other medical officers. 245 cases had occurred in the Casualty Hospital. Seven persons had been attended to by the Humane Society branch of the institution. The receipts for the last year were £97. 10s. 6d. subscriptions, and a legacy of £50 minus the duty; the expenditure £73 for medicines, £40 the House-Surgeon's salary, £24 for the housekeeper, £25. 2s. 3d. for the Humane Society's men. Dr. Struthers was elected one of the medical officers.

APPOINTMENTS.

Dr. Bond has been appointed by the Queen to the Regius Professorship of Anatomy, and also as Reader in Physic, in the University of Cambridge, vacated by the death of Dr. Haviland.

MILITARY.—36th Foot. Assistant-Staff-Surgeon, George Frederick Bone, M.D., to be Assistant-Surgeon, vice Smith, who exchanges. Hospital Staff.—Assistant-Surgeon, Francis Smith, from the 36th Foot, to be Assistant-Surgeon to the Forces, *vice* Bone, who exchanges.

NAVAL.—Assistant-Surgeon Frederick F. Morgan (1845) to the Bloodhound, steam-vessel, tender to the Sampson, steam-frigate, at Devonport, for service on the coast of Africa. Surgeon William Looney, M.D. (1845), to the Apollo, 8, troop-ship, at Sheerness, vice Robertson, Assistant-Surgeon James S. Ayerst to the Queen; Assistant-Surgeon James S. Agent (1847), from the Hogue steam guard-ship at Cork, to the Queen, 116, flag-ship, on the Mediterranean station; James Young, M.D. (1851), acting, to the Cumberland, 70, flag-ship of Vice-Admiral Sir George Seymour, G.C.H., fitting at Chatham for the West India Station. Assistant-Surgeon J. W. Bradshaw, from the Amazon to the Royalist; Assistant-Surgeon W. Telfer from the Hastings to the Amazon.

UNIVERSITY OF LONDON.

MB. SECOND EXAMINATION, 1350.—EXAMINATION FOR HONOURS.

Physiology and Comparative Anatomy.

Bristowe, John Syer (gold medal) } Equal { St. Thomas's Hospital.
Growse Robert (ditto) } Equal { Guy's Hospital.

Hewitt, William Morse Graily, University College.
Shearman, Charles James, University College.

Surgery.

Bristowe, John Syer (scholarship and gold medal,) St. Thomas's Hospital.
Lewis, Robert Benson, (gold medal), Leeds School of Medicine.
Growse, Robert, Guy's Hospital.
Shearman, Charles James, University College.
Hewitt, William Morse Graily, University College.

Medicine.

Growse, Robert (scholarship and gold medal), Guy's Hospital.
Shearman, Charles James (gold medal), University College.
Bristowe, John Syer, St. Thomas's Hospital.
Lewis, Robert Benson, Leeds School of Medicine.
Hewitt, William Morse Graily, University College.

Midwifery.

Hewitt, William Morse Graily, University College.

M.D. EXAMINATION, 1850.—FIRST DIVISION.

Baines, Matthew, King's College.
Barrow, Edward Enfield, Guy's Hospital.
Birkett, George, Charing Cross Hospital.
Carlill, John Burford, University College.
Eade, Peter, King's College.
Edwards, William Thomas, University College.
Elam, Charles, Leeds School of Medicine.
Monckton, Stephen, King's College.
Ransom, William Henry, University College.
Sankey, William Henry Octavius, St. Bartholomew's Hospital.
Wilks, Samuel, Guy's Hospital.

SECOND DIVISION.

Ayre, William, London Hospital.
Heale, James Newton, St. Thomas's Hospital.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted members Friday, January 17th, 1851:—Arthur Bell, Banagher, King's County; Henry Strangeways Rounsell, Bridport; Thomas Husband, Madras; Robert Caane Roberts Jordan, Teignmouth, Devon; John Lacy, Woolwich; John George Porter, Peterborough, Northamptonshire; Thomas Morley Rooke, London; Harry Octavius Thornold, Bombay; Henry Mable Watson, Clitheroe, Lancashire.

The following gentlemen were admitted at a special meeting of the court of examiners, on the 23rd of January:—Messrs. Thomas Coke Higgs, St. George's, Bermuda, and Edward Higgon Evans, Treffgarne Hall, Haverfordwest.

SOCIETY OF APOTHECARIES.

Gentlemen admitted members Thursday, Jan. 16th, 1851:—John Cromwell Blackford, Bromsgrove; Alfred Kitching, Hull; George Bacon Sweeting, Dorset; Edward George Wake, Hull.

Gentlemen admitted members Thursday, Jan. 23rd, 1851:—Edwin Henry Bolton, London; Wm. Chapman, Sedbergh; George Elin.

OBITUARY.

January 8th, at Chertsey, James Robert Cole, Esq., surgeon, aged 39.

January 17th, at the residence of his son in the city of York, in his 80th year, William Travis, M.D., of Scarborough.

January 21st, at 7, Taunton Place, Regent's Park, aged 36, John Dymock Scale, M.D., M.R.C.S., and L.A.C.

BOOKS RECEIVED FOR REVIEW.

Observations relating to the Science and Art of Medicine, by William Wegg, M.D., Cantab., Physician to the St. George's and St. James's Dispensary. London: John Churchill.

The Philosophy of Vital Motion, by Charles Bland Radcliffe, M.B., &c., Lecturer on Botany at the Westminster Hospital. London: John Churchill.

The Anatomist's Vade Mecum, by Erasmus Wilson, F.R.S. Fifth edition. London; John Churchill.

Braithwaite's Retrospect, July to December, 1850. London: Simpkin and Marshall.

The London and Provincial Medical Directory, 1851. London: John Churchill.

Lectures on Clinical Medicine, by J. H. Bennett, M.D., F.R.S.E., Fellow of the Royal College of Physicians, &c. &c., No 3.

Remarks on Insanity: Its Nature and Treatment, by Henry Monro, M.B., Oxon., Fellow of the Royal College of Physicians, Part II. London: John Churchill.

Excise Duty on Paper, Considered as Affecting the Employment of the Poor, the Grievances of the Manufacturers, and the Injury to the Consumer, by T. B. Crompton. Pamphlet.

Additional Observations on the Nitrate of Silver, with Full Directions for its Use as a Therapeutic Agent, by John Higginbottom, F.R.C.S., &c. &c. London: John Churchill

Introduction to the Tempest Prognosticator, by George Merryweather, M.D., Whitby. London: Whittaker and Co.

The Journal of Psychological Medicine, Jan, 1851.

Monthly Journal of Medical Science, Jan., 1851.

New York Journal of Medicine, Nov. 1850.

London Journal of Medicine, Jan., 1851.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

NOTICE TO MEMBERS.

Gentlemen who have not yet paid their subscriptions for the current year, or who are in arrears, are requested to forward the amount due either to the Secretary of the district in which they reside, or to the Treasurer or Secretary of the Association at Worcester.

The attention of Members is particularly requested to the following resolution, unanimously agreed to at the late Anniversary Meeting, held at Hull on the 7th and 8th of August, 1850:—

"But if any Member's subscription remain unpaid twelve months after it shall become due, the *Medical Journal*, and other publications of the Society, shall be withheld from such Member till his arrears be paid; and when any Member has been in arrears of subscription for the *space of three years*, application shall be made for the same by the General Secretary, and if the arrears be not paid in *three months* the name of that Member shall be omitted from the list of Subscribers; but the omission shall not be deemed, either in honour or equity, as releasing any gentleman from the subscription owing during his Membership."

Members who wish to propose Associates are reminded, that as the subscription commenced on the first of January, it is the most convenient time to introduce new members.

It is also particularly requested that all post-office orders should be sent either to the Treasurer or Secretary, who alone have the power of giving receipts.

JAMES P. SHEPPARD, Secretary.

Worcester, Jan. 21st, 1851.

ERRATA.—In Dr. Duncan's paper in our last number, page 31, col. 1, line 20, the word bronchitis has been placed instead of *bronchiectasis*; and in the same page, col. 2, line 10 from the bottom, the word bronchitis has been again wrongly substituted for *bronchiectasis*.

TO CORRESPONDENTS.

Communications have been received from Mr. Harvey, Mr. Patterson, Mr. Mallaline, Mr. Veasey, J.D., Mr. Sweet, Mr. Brown.

Chirurgus de Heywood is informed that Mr. Crompton's paper "On Burns and Scalds" is now in the hands of the printer, and will be published in the next volume of the "Transactions."

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho. But all communications respecting the routine business of the Association should be forwarded to James P. Sheppard, Esq., the Secretary of the Association.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq.,
Downing College, Surgeon to Addenbrooke's Hospital.

Lecture XXIX.

Malignant Tumours or Cancers.

Definition of the term malignant as applied to tumours; general characters of malignant tumours; contrast between malignant and simple tumours; some points of relation between the two: microscopical characters of malignant tumours; fibrous stroma and cancer-cells; different proportions in which they coexist: either may exist alone; relation of the fibrous stroma and the cancer cells to the natural structures; effects of cancer upon the adjacent tissues, producing atrophy of some and hypertrophy of others; the latter exemplified by thickening and ossification of periosteal fibres, by osteoids, by thickening of the muscular coat of the intestines, &c. Explanation of the common absence and occasional presence of capsules around malignant tumours; softening; ulceration, &c.; characters of cancerous ulcers; their difference from phagedenic and scrofulous ulcers.

The "malignant tumours," or "cancers," for we will regard the terms as synonymous, constitute one of the most important classes of disease that can occupy the attention of the pathologist, both on account of their frequent occurrence and their baneful effects. The investigation of them is attended with many difficulties, because all the other morbid processes we have been considering are involved in them to a greater or less extent, and serve to complicate their pathology, in addition to the new and striking features which they present. These latter have, perhaps, attracted rather too much attention in recent as well as in more ancient times, and I cannot help thinking that many of the erroneous views which have been promulgated with regard to the nature of cancers, are due to the disproportionate stress generally laid upon its *peculiarities*; probably a nearer approximation to truth will be attained by allowing the *similarities* of cancer to other morbid products to occupy a larger share of our study.

It will not be in my power even to allude to many of the various theories which have been and which are now maintained upon the subject of cancer. I can only pretend to give you the general deductions I have formed from a good deal of observation, reading, and reflection. Those deductions are not meant to be final conclusions either for yourselves or for me; they are merely observations made in passing over a wide and intricate tract of pathology. You must go as far as you can over the same ground and form your own opinions for yourselves. One of the first difficulties that meets us in our progress is the signification of the term "malignant," and the necessity of defining what kind of disease should be included under so ominous a name. Upon this point a vast deal has been written and a great many opinions expressed; nevertheless it would seem that, in reality, most pathologists and surgeons are very nearly agreed as to the practical meaning of the term. Perhaps if the word "destructive" be substituted, it will give you a clearer notion of the qualities essentially characterising a malignant tumour. We call a tumour "malignant" because it is destructive, that is to say, because it annihilates or destroys the natural tissue of the part in and near which it grows—the original tissue is lost and a new structure is substituted for it; it is still further destructive, inasmuch as the new or substituted tissue is peculiarly liable to decay, and, in consequence, ulcerates or mortifies, causing breaches or chasms in the frame which may increase to a very great extent. These two qualities may be said to constitute the leading features of malignant tumours or cancers; first, the destruction or degeneration of the natural tissues in and near which the tumour grows; secondly, the tendency to decay of the tumour itself. The degree in which these two qualities are manifested varies much in the different varieties of malignant tumours, indeed it would be asserting too much to say that they are altogether confined to the members of this class; but without question they are so generally evinced in a marked degree by cancers, and are so little displayed by any other kind of tumour, or indeed by any other kind of disease, that we may fairly make them the tests by which this class of morbid products is to be distinguished.

I cannot help thinking that in the present state of our knowledge we shall do more wisely in classifying morbid products according to the general characters they present, and their obvious influence upon the surrounding tissues, than according to their intimate structure as revealed by the microscope, or according to any theories deduced therefrom as to their mode of development and growth. Doubtless it will be found, indeed it has already been found to a considerable extent, that a certain uniformity of structure pervades the different members of this and the other classes of morbid products which are allied by their general features and their progress; and we gladly call in the aid of the microscope to carry our investigations beyond the bounds which the ordinary means of observation enable us to attain; but the many difficulties and sources of error necessarily intertwined with the science of microscopy, should warn us against too implicit a reliance on the results which it has hitherto afforded in morbid anatomy. I do not wish in the slightest degree to derogate from the usefulness of this new appendage to our science. It has already done wonders, and to it probably we must look, in great measure, for the further advance of pathology and anatomy; it has come to our assistance just at the time when our former means of observation seemed to have done their utmost. But it is quite possible to overestimate the value of its present results, and I think we do so in making them the basis of our classification.

If a disease presents the usual general features of cancer, if it exhibits a tendency to assimilate and destroy the adjacent tissues, and to undergo spontaneous ulceration itself, surely we ought not to reject it from the family of cancer because its minute anatomy does not appear to correspond exactly with our observations of the other members of the class.

There are several other peculiarities observable in malignant tumours of no less practical importance than the two features just specified; but they are less constant, and therefore less strictly to be regarded as characteristic. Such are their frequent appearance in the internal and more highly organized, as well as in the external and simpler structures; their common occurrence in several parts and in various structures of the same individual, as well as their liability to return after complete extirpation, from which we infer that some particular constitutional condition, some "dyscrasy," is associated with them, either as cause or effect; their determined progress, which is for the most part rapid, steady, and uncontrollable, terminating only with the life of the patient; their want of resemblance to any of the natural structures of the body, and the general uniformity of their appearance and progress in whatever part of the body they are found.

These features of malignant tumours become most striking if you contrast them with those commonly observed in simple tumours. The latter, with few exceptions, have their seat among the ordinary tissues; very seldom are they found in the internal organs, or in structures of high organization, and they commonly bear a more or less close resemblance to the tissues in which they are found, being composed either of fat, cellular or fibrous tissue, cartilage, or bone; they increase slowly, are scantily supplied with blood, and attended with little or no pain; they do not, except by their mere bulk, interfere with the movements of a limb, or modify the nutrition of surrounding parts. In the majority of cases their limits are well defined, and they may be removed without the loss of any appreciable portion of the natural constituents of the frame, and with little fear of a return of the disease, while the chance of their appearing in any other part of the body is so slight as scarcely to form an item in the calculations relative to an operation. They are compatible with perfect health, and do not commonly shorten life, or indeed exert any evil influence on the person or the part in which they occur; neither do they, as a general rule, exhibit any inherent tendency to decay. When softening does take place it is often the result of some accident; or if it be spontaneous, it is attended with no mischievous results; on the contrary, it may lead to the disintegration of the entire mass and its elimination from the system, so inducing a cure. Lastly, simple tumours often remain quiescent for years; sometimes they waste away, or undergo calcareous degeneration. How different is the account we have to give of scirrhous or encephaloid tumours. Affecting every organ and every tissue almost indiscriminately, they preserve their peculiar characters wherever they occur. Bone, muscle, tendon, gland, and skin, are involved and destroyed by the all-prevailing and all-assimilating mass; the natural and morbid structures become blended together, so that their respective limits can scarcely be discerned, and the one cannot be removed without interfering with the other; functions are suspended, and the movements of the part impaired. These tumours, for the most part, grow quickly, are freely supplied with blood, and are attended with a good deal of enlargement of the neighbouring vessels. They are often very painful, and if the general health has not been impaired in the first instance it is soon found to suffer, more particularly when they begin to soften and ulcerate. The breaches caused by ulceration are hardly ever closed; and while the softening and ulceration proceed from the centre, the disease invariably advances at the circumference. Thus the work of destruction goes on from point to point till the functions of an important organ is arrested or the patient sinks under the continual discharge and pain. The difference between these two classes of disease are, it is clear, from this short summary, decided enough to warrant their being designated by the respective terms "simple, or innocent," and "malignant."

Nevertheless, these diseases, so different and widely removed from in one another in the various and important features just specified, have their analogies and their points of contact. Indeed there are members of the two classes approaching so nearly to one another as to have occasioned a perplexity with regard to their proper position; and some pathologists have endeavoured to get rid of the difficulty by instituting a third and intermediate class under the name "cancroid" or "semi-malignant." I do not think that any advantage is gained by this further sub-division. It has rather the effect of thrusting the two classes more widely apart, instead of assisting us to view them in their relation to one another. Some of the most remarkable instances to which I now more particularly allude, as in some degree forming a connecting link between simple and malignant disease, are furnished by the cutaneous warts. In them it is not easy, either practically or pathologically, to draw the line of demarcation between simple hypertrophy and genuine cancer; and they present, therefore, features of peculiar interest, by studying which we are perhaps more likely to obtain a correct knowledge of the pathology of cancer than in any other way. Your attention will accordingly be directed in an especial manner to them, as well as to certain other instances which seem to occupy a somewhat similar position, for there are many other examples, besides those furnished by the cutaneous disease, of a hypertrophic condition of one or more of the natural constituents of the tissues forming an important element in cancer.

Having said thus much to give you a general idea of the characters of those tumours to which the term cancer is usually applied, I will now enter more closely into the details of their anatomy and pathology.

The appearances which cancers present to the eye vary a good deal, and will be described more particu-

larly when we come to speak of the several species of the class. It is generally acknowledged that these appearances are not sufficiently definite to permit even the practised eye to decide with certainty whether a tumour be simple or malignant. The application of the microscope to pathology has, therefore, been regarded, and doubtless rightly regarded, as affording another and a surer test. It is a test that cannot be relied on till the observer has given much time and attention to its use, as those know best who are most experienced in it; and we must not be led into the error of assuming that there is only one structural type of cancer, and that all specimens are to be rejected from the family which do not come up to that standard. At present the science is too much in its infancy to admit of our dogmatising upon the information it affords without giving their legitimate weight to other considerations; with this warning I will give you, as far as I can, the general results obtained by those who have paid most attention to the subject.

It is commonly agreed that the greater number of cancerous growths consist of a fibrous stroma, disposed in meshes which contain nucleated cells, nuclei, and granules, together with a thin serous or gelatinous fluid. The proportions in which these three elements are combined, vary greatly in the different species of cancer. In the scirrhous or hard cancer, for instance, the fibrous structure predominates; in the encephaloid or soft cancer the cells are more abundant; and the colloid or gelatiniform cancer is composed in great measure of jelly-like fluid. Neither of these elements examined separately are found to exhibit any decidedly distinctive characters, the peculiarity of the cancerous growth consisting not so much in the materials of which it is composed, as in the mode of their arrangement.

The fibrous basis of cancer resembles much the common areolar or fibrous tissue, being made up of bundles of compressed wavy filaments, intermixed with which are often to be seen well developed curled filaments of elastic tissue; these filaments are supposed to be formed by the process of cell-development, in the same manner as the natural fibrous tissue, and fusiform corpuscles, apparently undergoing the changes tending to this result, are occasionally seen intermixed with the filaments. In some cases, however, this fibrous basis cannot be shown to possess so distinct a structure; it may present only a dense amorphous appearance, not unlike coagulated fibrine or lymph; or the growth may be composed of a mere jelly-like substance, traversed by a few delicate fibres, and interspersed with granules and nuclei, the fibres being formed through the intervention of the nuclei without there being a trace of any intermediate development of cells. This last condition has been observed more particularly when the tumours were recent, of rapid growth, and of soft structure. The cells just spoken of as constituting the transitional stage between nuclei and fibres, are supposed to be quite distinct from the so-called cancer-cells presently to be described. Sometimes the fibrous structure of cancer presents very much the appearance of unstriped muscle. The mode of arrangement of the fibres varies a good deal; not unfrequently they exhibit nearly the same general disposition as that of the fibrous or areolar tissue in the part where the tumour grows, but in many cases we cannot discover any relation of that kind. In cancer of the liver they are often seen to form tough coarse bands radiating from the centre to the circumference of the tumour, and in the gelatiniform cancer they are disposed as membranes enclosing roundish spaces, in which the jelly-like fluid and the cells are contained.

It is a question of much interest in reference to the real nature of cancer, whether this fibrous element is in reality, as generally supposed, an entirely new production, or whether it is the result of some change—some morbid hypertrophy, or chronic inflammatory process—taking place in the natural cellular and fibrous tissue of the part affected. The observations made in the last few lectures with reference to the origin and mode of growth of simple tumours, warts, &c., will have prepared the way for a favourable consideration of the latter view, and there are many facts yet to be adduced in its support; at the same time it must be granted that there are some difficulties in the way of accepting it entirely. The arguments in favour of both these views will appear as we proceed.

The cell element of cancer has naturally proved an object of much interest, inasmuch as the essence of the disease would seem to be almost concentrated in it, the rapid growth and self destructive or decaying tendencies of cancer being to a great extent proportionate to, if not dependent on, the quantity of cells developed in the meshes of the fibrous stroma. Pathologists hoped, therefore, to find some distinctive structural peculiarities attaching to these cells whereby the nature of the disease might be recognised at once and with certainty. This expectation has not however at present been confirmed by observation: it is the opinion of those best qualified to judge that cancer cells do not present any decidedly characteristic peculiarities, that they vary in appearance a good deal, that in each of their different forms they resemble some of the primary cells of other tissues, and that in the form, which from its frequent occurrence in specimens of well-marked malignant disease might be taken as the type, they are not to be distinguished from the cells of cartilage or the cells composing the deeper layers of epithelium. Indeed some of the structures which present in a sufficiently well-marked manner the practical tokens of malignancy, do not appear to contain the cancer-cell at all as an ordinary constituent; such are some of the varieties of cancer of the skin and cancer of the muscular coat of the intestinal canal. The cells commonly found in cancers, which may be seen in the fluid scraped from a section of the morbid mass, and to which the name, "cancer-cells" has been applied, are larger than blood-globules, of about the same size or rather larger than pus globules, composed of a tolerably well-defined cell-wall, with one, two, or more nuclei, in which nucleoli may be often seen. The cell-wall is rendered transparent or dissolved by acetic acid, the nuclei being unaffected. The cells vary a good deal in shape, being round or oval, or

elongated at one or both ends into a caudate or spindle form, or they may send out processes from various parts of their circumference. It is the general opinion, that they do not, at least ordinarily, advance beyond the cell-stage of organization, that they are not transitional to any other form of structure, but that having attained to a certain size they are disintegrated, and their constituent atoms are returned to the fluid from which they were derived; or by a process of endogenous growth they may become the parents of other secondary cells formed in their interior; that is to say, their nuclei and nucleoli enlarging and converted into cells may fill up the interior of the parent, and at the period of its dissolution may become set free and undergo like changes in their turn, the materials for the growth of their nuclei being furnished by imbibition through their walls. Some authors have described the cells to increase by fissiparous gemmation, and Dr. Bennett speaks much of their occasionally undergoing a retrograding process; the nuclei disappearing instead of enlarging, the cell-wall shrinking, collapsing, becoming infiltrated or intermixed with oil, and ultimately resolved into fragments and granules. He finds the yellowish masses often seen in cancerous tumours to consist in a great measure of cells thus altered.

With regard to the nature of these cancer-cells, and their physiological relations to the fibrous element and to the natural tissues of the part affected, it is not easy to form an opinion. By some authors they have been looked upon as independent existencies, like entozoa or fungi, growing in the body and propagating themselves to distant parts through the medium of the blood by sporules which find their way into the circulating current, either through the delicate walls of the capillaries, or through openings in the small vessels. It seems to me on the whole most probable, that they are the result of some peculiar influence exerted upon the nutritive elements of the blood effused among the tissues by an altered or morbid state of the nutrition of the part, being in this respect, to a certain extent, analogous to pus-cells, which they also resemble, in their incapacity to undergo further organization; and in their being in terminal, not transitional, stages of development. The two morbid products differ, however, in the important particular that the cancer-cells possess the property of self-multiplication, absorbing and assimilating the elements of the blood, whereas the pus-cells are dependent for their increase on the continuance of the inflammatory process causing fresh exudations, endued with similar tendencies to those from which they sprang themselves. There are some circumstances, such as the accumulations of pus in certain cavities or abscesses, which render it probable that even the pus-cells exert a certain assimilative influence upon the fluid or even the solid lymph effused in their immediate proximity, but they do so only in a slight degree, and with a force scarcely comparable to that of the cancer-cell. This point of difference between the products of inflammation and the elements of cancer, is of great importance, and constitutes one of the most marked features of their distinction.

Besides the cells just mentioned, there are commonly found floating in the same fluid nuclei and granules, with perhaps other cells, such as those which are in process of development into tissue, pus-cells, &c. Oily matter, in the form of minute globules dispersed through the mass, is also a very usual constituent; and there are commonly found many elements not belonging to the cancer itself but to the structure in which it is produced, such as striated muscular fibre, fat, glandular tissue, &c. The blood-vessels are often of large size, and very numerous; they are generally admitted to be derived from an increased growth of the vessels naturally supplying the affected part.

It should be observed here of the two chief elements of cancer, that they are not only intermixed in very different proportions, but that they do not invariably coexist. In some few instances the cells alone are present, being infiltrated among the tissues of the affected organ, or they may be intermixed with lymph effused in consequence of inflammation taking place in a person who is the subject of malignant disease, or in whom the cancerous diathesis is strong. So on the other hand cases now and then occur in which a tumour, consisting only of fibrous stroma, without the intermixture of any cancer-cells, and resembling, therefore, a fibrous tumour, may exhibit the destructive and inveterate qualities of malignant disease. As a general rule, the rapidity of growth and the tendency to decay in a tumour are proportionate to the quantity of cells developed in it; they are greatest in encephalona, less marked in scirrhus, and least marked of all in those specimens of scirrhus where the fibrous element constitutes the entire mass.

The relation which the cancerous elements bear to the natural tissues, and their effects upon them, are points of so much interest, that we must again revert to them. It is evident that at first the natural and morbid structures are, to say the least, very closely connected together. Most pathologists agree that the cancerous matter is infiltrated among the original elementary parts of the parent tissues, and occupies nearly all their interstices; that in process of time the elements of the tissues become compressed, appear to be blended with the deposit into a homogeneous mass, and gradually become atrophied and disappear. Indeed the connection between the natural and the morbid structure is in some cases so intimate, the one being scarcely distinguishable from the other, as necessarily to suggest the idea that there may have been not merely a blending, but an actual transformation of the healthy into the cancerous tissue. This is particularly true in some of the glandular organs. In the liver, for instance, the first indication of the disease is commonly afforded by a mottled appearance, resulting from a slight discolouration of some of the lobules; they retain their proper shape and size, and their distinctness from the neighbouring lobules, but they are of white colour, and the natural components of the lobules are replaced by, if not transformed into, the elements of cancer. As the disease increases, adjacent lobules are affected, their structure is more completely altered, their individuality

lost, and they are fused into one mass. In the breast also the lobules which have undergone the cancerous degeneration for some time retain their natural outline, and their separation from one another by septa of areolar tissue. Even when the whole gland has become involved, we may sometimes trace the remains of the lactiferous tubes branching in the interior, and the fibrous septa penetrating the exterior of the morbid structure. It is the presence of these latter which bind the integuments down to the breast, and assist in producing the knotty tuberculated state of the surface often observed in cancer of the mammary gland; after a time both the lactiferous tubes and the intercurrent septa disappear, either wasting away, or becoming transformed into cancer, and no trace of original structure remains. I have used the word "degeneration," to express the change in these cases, because that change really seems to correspond in many respects with certain other alterations in the tissues usually described under that name, more particularly the fatty degeneration. Although aware that the best authorities are quite opposed to such an opinion, I cannot help thinking that the relation now alluded to is not one of mere coarse similarity, but that the cancerous and fatty degenerations are, to a certain extent, really allied in the mode of their occurrence.

However this may be, when once the cancerous change has commenced it is almost sure to spread. The assimilative energies of the morbid product are so intense that the neighbouring tissues yield under its superior force, their own nutritive powers are as it were prostrated, and they soon disappear in the same manner as the part first affected. Before being thus completely destroyed they are found in many instances to undergo certain alterations, such as atrophy or fatty degeneration, which indicate that their nutrition is impaired and that they are ready to fall an easy prey to the destructive influence which is encroaching upon them. Whether these alterations are entirely the result of that influence operating on them, though at a distance, or whether they are in part also the result of some inherent deficiency, which is the common cause both of the cancer and the atrophy I cannot say, but am inclined to think the latter is the case. At any rate it is a common thing to find bones affected with cancer in some parts, and atrophied or greasy at others; the mammary gland, which is the seat of scirrhus in some of its lobules is often shrunken or loaded with fat in others; sometimes you see, as in the specimen shown you on a former occasion, a small scirrhous lump under the nipple imbedded in a mass of fat, which occupies the seat and retains the shape of the mammary gland. In like manner, when a muscle is affected with cancer, the fibres contiguous to the morbid product, are often observed to be in a state of more or less advanced fatty degeneration; their transverse markings are indistinct or invisible, their nuclei imperfect, and they are pervaded with oil. Further, although the general wasting of the body, so constantly accompanying the progress of cancer may be occasioned by pain, discharge, and various accidental causes, it must be allowed that the disproportionate quantity of fat often found in such cases, both under the skin and about the internal organs, —that fat having a remarkable deep yellow colour—is attributable to some peculiar condition of the nutritive functions dependent on, or associated with cancer.

To this general rule of the association of atrophy with cancer there is a remarkable exception which claims our particular attention. I mean the frequent manifestation of hypertrophy in those septa of areolar and fibrous tissue which have been described as surviving for a time amid the desolation induced by cancer, and which may be traced for some distance into the morbid mass. The fibrous processes passing from the skin into the mammary gland become thick, tough and contracted in cancer of the breast; and when cancerous tumours are situated under the skin in other parts of the body, they are often intersected by processes of thickened areolar tissue passing into them from the skin. The most striking examples of this change are afforded by the formation of malignant tumours between bones and their periosteal coverings. The periosteum is in such cases separated from the bone by the gradual increase of the morbid product between the two; but it for some time retains a connection with the bone by means of the fibrous filaments passing from the one to the other; these filaments traversing the cancerous substance, and stretched by it, become greatly thickened, and for the most part are ossified, in course of time giving rise to those plates and spicules which you may have noticed extending perpendicularly from the surface of a bone into a malignant tumour. That this explanation of the origin of the osseous fibres and plates in malignant tumours of bones is correct, was almost proved by a recent specimen which I had an opportunity of examining not long ago: it was a case of encephaloid disease of the femur in a young woman, and the several stages just described could be traced at different parts of the exterior of the bone. In one place the periosteum was just elevated from the surface of the bone; and the stretched connecting filaments, somewhat thicker and coarser than natural, were seen in great numbers passing from the periosteum to the bone through the intervening cancerous medium. In another place the separation of the periosteum was more complete, and the filaments failed to reach it; still they could be distinguished attached at one end to the bone though the other was lost in the tumour. Nearer the middle of the limb they were replaced by osseous fibres taking the same direction and evidently originating in the same manner. At a still later stage the osseous fibres would doubtless, like the other tissues, and like the bone itself, have yielded to the superior assimilative forces of the morbid product, and have disappeared. This hypertrophy and ossification of the stretched periosteal fibres, though most common in malignant tumours, is not peculiar to them. It is not found when the growth of the tumour has been very rapid, but is most marked in cases where the tumour has made comparatively slow progress, and has exhibited the other evidences of malignancy only in a moderate degree. In such a case the osseous substance

may constitute the chief portion of the tumour, forming large porous masses, which, when macerated, resemble pumice stone. The new bony matter under these circumstances is generally less dense and firm than true bone; sometimes it has scarcely the proper structure of bone, resembling rather an amorphous cretaceous deposit. It is not confined to the outside of the bone, for the cancellous texture in the interior is often solidified, and is sometimes rendered very dense and ivory-like by a similar process taking place in it. Tumours of this kind, where the osseous substance forms so large a portion, and the malignant qualities are only inactively displayed, have been described by Müller under the name "osteoid;" at least it appears to me that the tumours so named by him are of this nature. They sometimes attain to very large size and are most frequent about the extremities of bones, particularly the lower end of the femur.

Changes analogous to this hypertrophy and ossification of the periosteal fibres are afforded by certain other tissues when they are the subjects of cancerous infiltration. The lactiferous ducts already mentioned as occasionally persistent in scirrhous breasts are usually found to be increased in size. In a case of cancer of the skin described by Dr. Bennett* "the tissue of the dermis was considerably hypertrophied, consisting of curling filaments of elastic tissue, with a fibrous network, in which numerous loculi or round openings were observed. Some of these were completely filled with cancer-cells." The epidermis was hypertrophied, and the scales offered a striking resemblance to some of the forms of cancer-cell. They were, however, external to the fibrous tissue, whereas the true cancer-cells were situated within the meshes formed by it. Another very remarkable instance of the association of hypertrophy with cancer is afforded by the stomach and intestinal canal, more particularly by the muscular coat, which you may observe by examining these specimens of scirrhous disease of the pylorus. In this one the mucous membrane is a little thickened, pulpy, vascular, villous or warty, and preternaturally adherent to the muscular coat. The peritoneum is also thickened, and in like manner adherent to the muscular coat; the layers of areolar tissue between the three tunics being also thickened and indurated. The chief changes have taken place in the muscular coat, which is more thickened than either of the others. It is tough and hard, and is composed of parallel bands or fibres, of pale greyish colour, placed side by side, closely compressed together, and united by more opaque intervening septa of indurated tissue. The disease terminates abruptly at the duodenum, diminishing gradually in the opposite direction, where the fibres and bands become less thick and less adherent to one another, though they are somewhat hypertrophied throughout the specimen. This and some of the other specimens have been dissected for the express purpose of showing, which they do clearly, that the alternate pale and opaque bands, giving a striated appearance to the section, are composed of the muscular fibres and the intervening areolar tissue, in a thickened, indurated, and compressed condition. In one instance this condition exists throughout the whole stomach; and we occasionally meet with tumours of considerable size, composed of the muscular coat thus altered and projecting into the cavity of the stomach. The physical characters of this change are so obviously such as I have described that some pathologists have found a difficulty in supposing that it can have any near relation to cancer; while others, not finding the part to possess the requisite microscopical structure, have concluded it to be a different disease. For my own part I am fully persuaded that the change in question, if not of genuine malignant nature itself, is most intimately related to cancer and entirely dependent upon it, It is almost always found to be associated with undeniable cancer in the mucous membrane or in the adjacent absorbent glands; and after a time the striated appearance is lost, the muscular and cellular structures being blended together into one homogeneous mass, which is subject to decay and ulceration in the same manner as the other forms of cancer. Moreover, well-marked cancer-cells have sometimes been seen infiltrated into the mass so formed. So far as I have been able to ascertain, this change is confined to the pale unstriped muscular fibre; I do not know of any instance in which the more highly developed form of that tissue was affected in a similar manner.

It seems to be the general result of the preceding observations that the higher or more organized tissues—the striped muscular, and the glandular—are commonly affected with atrophy and degeneration in connection with cancer, and that the more simple and less organized tissues—the unstriped muscular, the cellular, and fibrous—being less amenable to the destructive influences of cancer, are often hypertrophied or thickened by its first impression. We frequently find the two effects simultaneous in the same organ; the glandular element wasting, becoming fatty, or replaced by cancer-cells, while the fibrous element is increased to many times its natural thickness. You will not forget that the latter also does, after a time, yield to the destructive influences of the disease, being impregnated with cancer-cells, or infected with the general tendency to decay and ulceration. To what extent may not the lower tissues thus hypertrophied contribute to form the fibrous basis of cancer? At any rate the occurrence of this change in them deserves particular attention, and acquires particular interest, when taken in connection with the remarks made in former lectures with regard to the nature and origin of simple tumours.

You will understand that malignant tumours increase in size, partly by the assimilation of the neighbouring tissues to themselves, and partly by the hypertrophy of certain elements of those tissues, as well as by the development of new elements, the cancer-cells, &c., in their substance. Sometimes one and sometimes another of these modes of increase has the preponderance, which explains the fact that tumours of this species may or may not be invested with capsules. As a general rule,

* Bennett on Cancerous and Cancroid Growths, p. 15.

the cellular and other structures from which the capsule would be formed are involved and destroyed by the advancing growth; there may be no distinct line of limitation between the morbid and the healthy structures, much less any compressed layer of areolar tissue, such as we should call a capsule, separating them from one another. There are cases, however, where, owing to the immoderate cell development and internal growth in the tumour, it increases in bulk so much more rapidly than it destroys the neighbouring tissues that the latter are distended and compressed and form a capsule over it. This, of course, is most likely to take place when the structures around a tumour are loose and easily displaced, so as to offer little resistance to the expansion of the growth. Hence we commonly find that encephaloid tumours growing in the axilla, about the kidneys, and in other similar parts, are invested with well marked capsules in all respects like those which generally enclose simple tumours.

When you cut open a cancerous tubercle, you will often find that, at or near the middle, it is softened or converted into a more or less diffluent pulp; and if such a part be examined more closely, it is seen to have lost all regular structure, and to be composed of fragments which appear to be the disorganised remnants of cells and tissue. The softening depends, probably, upon a failure of the nutritive powers taking place to such an extent that the component atoms are no longer held in those structural relations into which they had been thrown, and in which they had been maintained by the vital or nutritive forces of the growth. It commences naturally at the part first formed, viz., the centre of the tubercle, and is similar to the softening that takes place occasionally in simple tumours, or more frequently in scrofulous deposits and tubercles, and is similar also to the softening and disintegration of the natural structures often induced by inflammation. Though occurring in cancers, for the most part, as a regular or natural process, it may be induced by any cause which prematurely impairs their vital energies, such as an attack of inflammation or a blow. Strange and paradoxical it seems that these same morbid products should possess such irresistable assimilative influence over the surrounding tissues, and should be so unable to maintain their own existence, so liable to decay and dissolution.

The softening may commence at one or more points, and sometimes leads to the formation of several small cavities in various parts of the mass, containing a turbid fluid which often looks like pus and may contain pus corpuscles. Indeed the process frequently resembles and is associated with suppuration; the smaller cavities coalescing into a larger one which approaches the surface like an abscess, bursts through the skin, and leaves an ulcer. When the cancer is situated near the skin, the softening commences on the superficial side, and takes place earlier than when it is deep-seated. This breaking up of the morbid mass is usually attended by some inflammation of the surrounding tissues with effusion of lymph uniting them together and rendering them a more easy prey to the ravages of the disease. At the same time the adjacent lymphatic glands are commonly observed to become inflamed, and to participate in the malady, if they have not before done so. It is by no means uncommon for inflammation in the surrounding tissues to precede the softening of the cancer; indeed it sometimes is contemporaneous with the earliest appearance of the disease, and attends it through all its progress so assiduously that some pathologists have regarded cancer to be only one of the multiform results of inflammation. The cavity or ulcer commencing in the manner just described continues to increase by the progressive softening and disintegration of the neigbouring cancerous tissue, so that particle after particle is separated and forms a component in the discharge; the disease still advancing in the circumference while the dissolution of the mass is thus going on at the centre. In this way huge caverns are sometimes formed, and large parts of the body destroyed. Sometimes the work of demolition proceeds at a greater rate, mortification succeeds to ulceration, and considerable masses are detached. Now and then, in consequence perhaps of a slight inflammatory attack, the whole mass appears to slough away and leave a clean surface behind; but the hopes of a cure thus excited are almost always doomed to be disappointed by the reappearance of the disease in the sides of the chasm from which the slough has separated.

The cancerous ulcer is distinguished from any other, inasmuch as it is preceded by the substitution of the cancerous structure for the natural tissue of the part affected; the substitute structure being indued with a power of growth and a remarkable assimilative influence over the adjacent tissues. Certain other kinds of ulcer, such as the phagedenic ulcers and cancrum oris, seem to approach to the malignant type in their determined progress, and in the mode of their increase; but they are not dependent, so far as we know, upon a previous structural alteration corresponding with that of cancer. In the scrofulous disease a structural alteration does often precede the ulcer, and bears many resemblances to the cancerous change; but the new product does not exhibit the evidences of an inherent power of growth, neither is it attended with any very marked assimilative or destructive tendencies. The discharge from a cancerous ulcer is thin, dirty, bloody, and peculiarly offensive. It consists of the fluid element of the growth escaping from the areolæ of the fibrous stroma, together with decaying fragments of the structure; the rapid tendency to decomposition in the latter imparting to it, no doubt, its fœtid odour. It is often intermixed with blood, and occasionally with pus. You cannot usually distinguish any cancer-cells or other definite structure, because the elements of the morbid mass are, for the most part, distintegrated before they are separated. The non-existence of cancer-cells in the discharge collected from an ulcer is, therefore, by no means to be regarded as conclusive evidence of the absence of malignant disease.

Some of the peculiar appearances which the cancerous ulcer presents are due to the combination in the same structure of a tendency to grow and a tendency to

decay. In some cases the former has the preponderance, when the surface of the ulcer is raised, granular, or warty, with an everted edge; perhaps the mass shoots forth through the skin as a large and overhanging fungus, or it forms a great tumour extending for a considerable distance under the skin. When, on the other hand, the decay and ulceration proceed rapidly, a large excavation, with raised sharp edges, is the result.

ON THE EXAGGERATION OF IDEAS

RELATIVE TO

CERTAIN SANITARY TOPICS.

By DANIEL NOBLE, Esq., M.R.C.S.

Read at the Conversazione of the Royal Institution, Manchester, Dec. 11, 1850.

There exists a power in new ideas which, as the novelty ceases, the ideas themselves do not maintain. Let opinions or conclusions be boldly advanced and perseveringly promulgated at variance with those which, time-honoured though they be, exert but a measured and steady influence upon society, and it will be seen that, for a season, they agitate the minds and determine the actions of their votaries to a degree far beyond what is noticeable in after periods. This is the case with doctrines the truth of which becomes ultimately demonstrated; and yet to a much greater extent with the fleeting vagaries or the half-truths of successive epochs. Undoubtedly this power of novelty is a great fact in universal nature; we recognize it in all classes of phenomena; it is a fact, moreover, everywhere witnessed as qualifying physical, moral, and social agency. Look at the workings of vegetation on the final disappearance of a retarding frost; how notable is the progress when the earth and the air become newly influenced by the genial warmth of a kindly spring. See the energizing influence of great moral truths, observable in so remarkable a manner on first being realized vividly by communities or individuals. We only need for one moment to reflect upon the past history of society to perceive that all its extraordinary commotions and upheavings have been preceded by, and are traceable to, the influence of new ideas. And although this important truth is susceptible of the plainest illustration by adverting to experience on the widest scale, a careful inquiry will yet show us that, in every department of thought and action, even the most minute—the same fact exists; all things attesting, indeed, the unwonted force, the exaggerated influence of ideas in their freshness.

In all matters which involve considerations of life, health, and disease the susceptibility of mankind to the influences of novelty is very striking. Let an idea for instituting improved modes of cure, or for prolonging life, be propounded, with even moderate plausibility, and see how large numbers arise to catch at it. And no experience of the falsehoods or the mischiefs which empiricism exhibits in its successive phases, leads to a popular recognition of its fallacies or its dangers. Each generation witnesses the rise and fall of numerous systems of quackery; yet faith revives always in the latest, and multitudes do it homage. Amulets and sympathetic powders constitute the illustration in one age, as galvanic rings and infinitesimal doses do in another. No matter for the inconsistencies and contrasts which impudently-advanced innovations present, novelty has always its charms for a time. If *brandy and salt* fail to realize the sanguine expectation of individuals, they will probably seek, with corresponding avidity, for relief in its opposite—*cold water*. And so it is ever. *Newness* strikes the *ignorance* of mankind, and *wonder* moves the world—a lever more potent than good sense, even in the nineteenth century.

A fact must here be kept in mind:—Whilst the influence of false ideas perishes very generally with their novelty, the power of those which are true for ever endures. Yet these latter display an energy very frequently in their birth which is not permanently sustained. But this phenomenon is further observed. Men becoming newly conscious of some extraordinary agency, proceed in their admiration to invest the source of it with attributes beyond those which are properly its own, just as certain nations of Pagan antiquity were led to imagine that a true divinity inhered in the visible source of light and heat. So what is true becomes overlaid and disfigured by that which is false, and in this way exaggerations arise of notions in themselves not unjust.

The exaggeration of ideas relative to certain sanitary topics, forms at the present period a striking exemplification of much that has been said. Men's minds at this time have become awakened to certain truths of importance—truths of which, twenty-five years ago, the bulk of the nation for all practical purposes was in ignorance the most profound. It must yet be acknowledged that from having, in a former era, attached little or no consideration to the physical conditions upon which health depends, the opposite error would seem now to have place. There is every disposition in the world amongst many to attribute the origin of almost every disease to some defect in the sanitary condition of the place of residence. Ailments with which, from the very nature of the thing, the mere dwelling-house, or the locality, can have had nothing to do, are ascribed very often, in accordance with the fashion of the day, to some possible fault in the drainage or the ventilation. Over-exertion of mind, depressing passions, late hours, irregularity in diet, and silk stockings, are entirely overlooked, whilst the presence of a ditch or a cesspool, some hundreds of yards off, is keenly detected, and possibly referred to as the origin of diseases rightly attributable to the influences ignored. A merchant capitalist has his days and his nights unceasingly harassed by care and anxiety, and suffers of course in his stomach and nervous system; hereupon he persuades himself fondly that all may be remedied, and be in future avoided, by removing a few miles from the town. Fevers and other contagious diseases decimate

at intervals the population of large places; it is rashly inferred from this circumstance that all such maladies are absolutely extinguishable by what have been called preventive measures—that is to say, by drainage and ventilation. The effects of bad food or scarcity, are but too often left out of the calculation. Indeed the speeches and the writings of some of our sanitary enthusiasts, would lead very near to the hope that all mankind, as the world advances, would die no longer of actual disease, but only of old age. We will contrast the existing state of popular sentiment with that which obtained some twenty years ago, before the public mind was systematically directed to this topic, and then we will attempt to strike a balance, in determination of the position which recent inquiries and discussions have apparently made good. Every one who is of sufficiently mature years will remember that, prior to late investigations, the subject of health in connection with residence was rarely deemed of sufficient consequence to occupy serious attention. The aspect of a house in relation to prevalent winds, the drainage of its neighbourhood, the ventilation of its rooms, or the quality of its water-supplies, only excited attention and thought under speciality of circumstances. When rheumatism seriously enfeebled the head of a family, or consumption deprived it of its flower and its hope, then the importance of a dry atmosphere and free ventilation became practically realized. Epidemic maladies ravaged the impoverished parts of our cities and large towns, but the miserable hovels in which the victims had lived were but little regarded in discussions of a remedy. Everything was believed to have been done if some hospital were established, or some physician sent to *see* the sick-poor at their own pestilential abodes; I say *see*, for *cure* or medical care were impossible under the circumstances. Overcrowding and filth were in ignorance allowed to do their worst, and abominations unspeakable degraded humanity to the level of the brute. For ailments generally, *drugs* were almost the only aids invoked. The necessity of placing the human organism in some understood harmony with external nature, if health were to be secured, was but little considered. In these respects, indeed, man seemed to know, or at least to think, less of himself than of the lower animals, over whose physical condition the elements were at all times known to exert a paramount influence.

From such a state of practical imbecility the researches of the last few years have aroused the public intelligence. And facts and laws long comprehended in their general bearings by the scientific physiologist, have now been brought home to the consciousness of the many. And persons in exaggerated homage to a new and admired truth, would at this time render almost exclusively important what had heretofore been so much disregarded. Thus it has happened with sanitary topics, as with numerous others, that ideas have been estimated beyond their just value, considered alike in their intrinsic worth and in their extrinsic relations, exemplifying in a striking manner that disposition in the popular mind which subjects it to so largely to the sway of novelty.

It has been established and placed beyond doubt, that towns are less healthy than country places. It has been shown that the average age of death in the former is lower than in the latter, and that a greater proportionate mortality takes place annually in urban than in rural districts. Further, it has been made certain that epidemic and contagious diseases are much more destructive in towns than in the country. In order, however, that the fundamental truth which these facts disclose should be correctly seized, the facts themselves must be submitted to some analysis; and, this being done, the result is to show that what ordinarily is affirmed of towns generally, is true only of particular localities. Thus, the lower average age of death in towns than in country places, is obtained by including the narrow streets, courts, and alleys, where overcrowding, filth, destitution, drunkenness, and neglect of young children, form causes constantly operative in the destruction of human life. When districts occupied by the middle and more opulent classes are selected for the investigation, to the exclusion of pauperised localities, little or no difference is discoverable between such places and the country. The annual mortality, moreover, under such circumstances, is not proportionately high. And it is a fact, that diseases which diffuse themselves, more especially under bad sanitary conditions, no more spread nor produce greater fatality, in the better parts of a town, than they do in the country. Let the epidemic fever of 1847 furnish the illustration. *Typhus*, in Manchester, raged during that year with thrice the severity of any visitation of the kind; yet it never became prevalent in any of our moderately-conditioned streets. If some few individuals became the subjects of attack residing in localities raised above the pauperised, it was from contagion imbibed through habitual attentions to the sick, and from such persons the disease never extended itself. I was furnished myself with unusual opportunities for observing the several circumstances of that memorable epidemic, and I do not know of a single instance where, in Manchester, the fever was transmitted to another from a patient dwelling in any of our better class streets; proving, most amply, that a very moderate ventilation is capable of extinguishing the virulence—the zymotic property—of the typhus poison. It would carry me beyond limits and exceed altogether the present design to enlarge upon this theme. I will simply reiterate the conclusion, that epidemic and contagious diseases neither destroy life, nor imperil the constitution in the well-conditioned parts of a town, more than in rural districts.

Facts and considerations like the foregoing, as well as a more particular and intimate experience, will authorize the assertion that, under the circumstances in which mankind at large are placed, and with reference to the human constitution generally, towns, as such, need not be less healthy than the country; and that, in point of fact, a well-selected dwelling in most of our great towns as they actually exist, will, in an immense majority of instances, be found just as conducive to health and longevity as one that is strictly rural. I say in an immense majority of instances, because, in a subject of this kind, no rule that can be laid down will apply

universally; the truth being, that, to some constitutions, the country, and to others the town, is the most advantageous. With large numbers the difference is neither to be realized nor appreciated.

That I may make this part of the discussion a little more intelligible, I will briefly state and explain a point of doctrine in physiology, which is this:—True health consists in the harmonious performance of all the functions of life, and harmony in this respect is secured and promoted by adapting the several organs and systems of the body as much as possible to the external conditions upon which their just exercise depends. Thus the lungs need pure air, the stomach good food, and the brain and nervous system require that every influence which affects the consciousness should be agreeable. I do not here state the whole case, but only what the occasion would appear to demand. Now, if there be a defect or a vice in any of the conditions just adverted to, the result must certainly be more or less to injure the health. The effect, from littleness of the cause, may scarcely be appreciable, but undoubtedly some result of a prejudicial character must always ensue from any deviation from the strict requirements of health.

To apply this doctrine. Certain constitutions require more especially that the inspired air should be pure, in order that the health be sustained in full measure; in such instances, a country residence will generally be found the best. This is most frequently the case in scrofulous habits of body, particularly if the temperament be phlegmatic. Young children almost always flourish more in the country than in towns. It must yet be noted that, in very exposed situations, there is more liability to inflammatory disease, and a greater violence upon its taking place. These countervailing considerations, however, can very well be obviated by corresponding watchfulness and care.

Now, on the other hand, there are persons so constituted, that health depends much more upon moral and social influences than upon any extraordinary advantages affecting the respiration. Such individuals will often enjoy much better health in the town, or the immediate suburbs, than in the country; always supposing that some fair judgment have been exercised in the choice of a dwelling-house. Where the mind is active and the disposition social, the tranquillity of a country life, and its comparative loveliness, operate prejudicially upon the brain and nervous system, and thus health becomes deteriorated at its source. It is under circumstances of this kind, that the invigorating effects of a temporary London life are often witnessed, when dissipation and excess do not antagonize them.

To hard-working persons whose days are actively engaged in the commerce and busy pursuits of a town, it is an unmitigated advantage to have lodgings in the country. Yet, where the permanent residence is rural, the wives and the daughters very often sustain detriment from want of due activity in the brain and nervous system. In such instances there is an absence of that proper succession of agreeable impressions upon the mind, so essential to that harmonious action of the organism which constitutes true health. And so it is universally: human nature must be estimated in its totality in all questions of its well being. The functions severally demand an appropriate *pabulum* or sustenance, and however excellently disposed may be the external relations of any one portion of the organization, health will fail if the beneficial action of some other be prejudiced.

I will, in this place, reiterate the facts and the inferences which I conceive to have been made out by recent sanitary investigations:—It is the poverty-stricken, over-crowded, and ill-constructed parts of large cities exclusively, that supply the evidence which renders urgent the demand for sanitary reform; the well-conditioned streets and suburban localities are not sensibly injurious to health, under ordinary circumstances; and the question whether particular individuals will be benefitted by a country or a town residence, is a matter to be determined by the specialities of each case.

It may be contended by some persons that, however plausible much of the foregoing may appear, popular experience and medical prescriptions are alike opposed to the idea that towns, under any circumstances, are as healthy as the country. It may be said:—"See what happens when the body is exhausted, and the energies enfeebled, by protracted disease of almost every kind, the country invigorates and revives when medicine of every kind has only exhibited its powerlessness; the patient emaciated by fever, or other acute disease, but slowly convalesces till he removes from the town; the harassed dyspeptic consumes drugs and executes prescriptions innumerable, but finds no decided or enduring relief excepting in change from the air of a town to that of the country. Look, further, at the experience of persons not regarded as actually sick, how the appetite and the spirits, and the sleep, become improved during a brief sojourn some miles from the smoke of a city; nay, indeed, but notice the amelioration of health that will sometimes occur upon removal from a locality that is four miles from a town to one that is six." And so on: the illustration might be considerably extended.

The accuracy of such facts as the above may readily be conceded; they do not, however, affect the justice of my argument. In a large number of cases, it is undoubtedly true, that the physical qualities of the atmosphere as realized in certain rural districts, have an especially beneficial and curative action. In instances of exhaustion after acute disease, country air is almost essential to a sound recovery. Many unhealthy habits of body, moreover, are incorrigible by medicine, unless the patient breathe the purest atmosphere. It must yet be maintained, and the fact should never be lost sight of, that a leading element from which the advantages often flow, consists in the *change* of air; and think how much is comprehended within this well-used phraseology—temporary immunity from the ordinary cares of life, cessation of toil, daily recreation, novel scenes and agreeable society; circumstances all most conducive to the restoration of shattered nerves and broken health. Again and again have such agencies been seen to effect wonderful improvement in disease,

even where the *change*, so far as physical conditions are concerned, may have been for the worse, from country to town. The influences which attach to novelty are exemplified once more. It is certain—and no matter how the fact is to be explained—that mere change of air sometimes is advantageous to health, irrespective of concomitant circumstances acting through the mind. It is the same thing with food, as every one knows. Let the most delicate and the most nutritious viands be habitually and uninterruptedly employed, and a *change* abstractedly for the worse, will not only be relished but will improve the digestion. The *toujours perdrix* is endurable by no one.

Hence it happens that change of air so often accomplishes good after medicines have been tried in vain. It is a superficial judgment, however, which ascribes to the *place* the benefits that really flow from the *change*. Disappointment has often resulted when this judgment has been acted upon. Permanent residences have been established in the charmed locality, whereupon the fallacy has been detected. The spell has not long survived the novelty. Nervousness, biliousness, and sleeplessness, you have found to vanish upon a fortnight's sojourn at the coast; but that this fact should receive its just interpretation, you must seek out the anxious-minded, disappointed, and over-wrought inhabitant of the favoured spot, and you will find that he suffers very much as you did before you left home. Take him back with you to town, make him forget himself, and regard the world without, interest him with strange sights and novel circumstances, and your own atmosphere, pestilential as you thought it, will also seem to have disclosed a health-restoring charm. A very little reflection upon these principles will discover their application in much of the experience of daily life.

I would guard myself against being misunderstood. Whatever may be the case with the great majority of mankind, there are, as before stated, exceptional instances of constant occurrence, where town and country are not indifferent as places of residence. The chest, for example, in certain individuals, constantly suffers in towns, whilst in other persons the brain and nervous system become disordered in the country, developing the phenomena of hysteria and hypochondriasis. In some instances the lungs in summer need, for their healthy action, the pure air of the country, and in the winter the more genial warmth and protection of a town. The same diversity of requirement obtains with regard to the nervous system. Some cases of disorded function are relieved by the bracing air, and free respiration, procurable in the country; and there are others rather benefitted by the social and exhilarating influences of large cities. It is very much the same thing with derangements of the stomach. There are cases in which abstinence is good, and there are others in which generous diet for a time becomes desiderated. But all exclusiveness and *system* here, as elsewhere, are to be avoided. There is a parallelism between *vegetarianism* and ultra-sanitary enthusiasm.

Neither the origin of diseases nor their modes of cure can be vigorously set forth in axiomatic phrase, neither can their doubtful points be elucidated by adoption of some favourite speculation of a particular era. As a matter of fact, however, the prominent idea of the day is very generally invoked to explain phenomena with which it is deemed to have some correspondence. In accordance with this circumstance, the fancied elucidation of disease and current systems of empiricism, are determined very much by the course of thought that happens to be predominant in the popular mind. In an age of witchcraft, maladies spring largely from magic, and are curable by amulets. In a later age, science displays the wonders of electricity, galvanism, and magnetism; these strike upon the imagination. At the same time certain ill-understood conditions and actions of the nervous system engage the public attention; hereupon animal magnetism comes into fashion, is thought to shed light upon disease, and to furnish the means of cure. A fanatical teetotalism, ascribing diseases almost universally to alcoholic drinks, developes a water-cure of all saving efficacy. And in like manner the theory which would trace maladies without number to ash-pits, cess-pools, and streets, leads to a horror of towns, and would almost regard the country as Eden again realized. Such is the influence of ideas in their freshness: such is the power that attaches to novelty.

Diseases have certainly their origin in numerous other circumstances than those which mix themselves up with the dwelling-house; and the remedies, too, are correspondently diverse. Inherited fault in the constitution, vicious or defective diet, injudicious clothing, irregularity of life, and exposure to vicissitudes of temperature, constitute severally most prolific sources of ill health. Excessive thought, or mental idleness, violent passions, corroding grief, anxiety and suspense, and the common cares of life, form causes systematically productive of disease. In a community like the one in which we dwell, disappointments in business, and the anxieties of all kinds associated with it, are potent beyond expression in their undermining influence. I am very much inclined to think, that these latter circumstances, in some respects, exceed most other agencies in the destruction of health and the shortening of life.

There are diseases, moreover, which arise from the action of poisons; I do not refer to these in their proper forms, but to such as are subtle and not appreciable by the senses, and which produce epidemic and contagious diseases, and from which no sanitary improvement can furnish an absolute immunity. It is perfectly true that the virulence of most epidemics can be mitigated considerably by appropriate drainage and ventilation, but some will rage, and very destructively too, under every known physical condition. There certainly is not a more demonstrable fallacy than that which attributes diseases, like cholera and scarlet fever, to known and removable causes—a fallacy that has originated in the reasonings of persons having neither a medical education nor a medical experience, but one in which there is little or no participation amongst thinking members of the profession. Extended remarks, how-

ever, upon this branch of the subject, would very unjustifiably encroach upon the time of the present auditory.

It is conformable to reason, and corresponds with the lessons of experience, that remedies for disease, and for enfeebled frames, must vary with the circumstances of the individual case. Good air and effective drainage are of the highest importance certainly, and I should be sorry to interpose a thought in seeming opposition to the ameliorations in these respects to which public opinion is leading. I do not, however, see that the discouragement of preposterous expectations can have any unfavourable tendency; on the contrary, I should rather believe that future disappointment which always follows upon over-wrought anticipation, would be much more likely to bring about prejudicial reaction than any attempt to establish more moderate views. At any rate it is right that the case should be justly stated, and in all that has preceded this has been my aim, whilst denouncing exaggeration and eliminating that which is *false*, to give greater distinctness to, and render more appreciable, the *true*.

ON GOUTY AFFECTIONS OF THE EAR.

By WM. HARVEY, Esq., M.R.C.S.L.,

SURGEON TO THE ROYAL DISPENSARY FOR DISEASES OF THE EAR.

In my last contribution on the "Rheumatic Affections of the Ear," I stated that there were some that partook more of the gouty diathesis, and in which the seizure commenced with tinnitus, and not unfrequently also attended with otorrhœa. This latter symptom was commonly presented to the surgeon under very aggravated forms in some cases, either from a wrong diagnosis, or from stimulating applications having been used. I am also of opinion that if the disease be early ascertained, and the constitutional symptoms treated more decidedly, it is much under the control of the surgeon. Those whose attention have been directed to this department of surgery, must frequently meet with this disease, either affecting the ear originally or from metastasis, the latter action more frequently, and thus it behoves the surgeon to treat the case actively, as the organ is soon irreparably lost. In the more chronic affection, or where it takes place in the aged, if diagnosed, much relief may be afforded to the distressing tinnitus. I have selected a few cases which will be appended to the second part of this paper, some of which I have been fortunate to trace to the termination.

Arthritic inflammation of the ear attacks chiefly the fibrous and nervous structures of the organ of hearing, and appears simultaneously or alternately with the manifestations of gout in other parts. It occurs, therefore, sometimes as a sympathetic affection of contiguous organs which may happen to be in the neighbourhood of the organ of hearing, and are attacked with gout, sometimes as the product of gouty metastasis. Should the inflammation develop itself rather on the external division of the ear, the patient feels on the external ear increased warmth and an intolerable itching. The itching becomes constantly more insupportable, and at length passes into a burning, tearing, and pinching pain, which spreads on all sides over the entire circumference of the ear. In this case the patient complains of constant tinnitus, and occasional singing in the ear, and of hardness of hearing. These symptoms increase to a considerable degree after midnight, and become somewhat mitigated towards morning On examination the external ear presents an erysipelatous redness, feels hot, and is extremely sensitive to the touch. The entire surface of the meatus auditorius is found to present a redness, rather pale than dark, is entirely denuded of cerumen, or covered here and there with a dark brown, thin, and dried deposit of the same, and the membrana tympani of a dull appearance, traversed by some large vessels. Should the inflammation continue to remain at this low point, the epidermis of the meatus auditorius throws itself off in mealy scales or in larger portions, or becomes agglutinated with the cerumen of the ear, which now becomes secreted in more than the ordinary quality. If the inflammation becomes more intense, amid an exacerbation of pain, small abscesses or furuncles burst in the muscles of the ears and in the meatus, which eventually discharge a sanious pus. All inflammatory symptoms are gradually mitigated upon this, and are renewed only when an abscess makes its appearance. In old people there is observed simultaneously a considerable swelling, which spreads over the parotid and the mastoid process, is associated with a rose-coloured inflammation of the skin and cellular tissue, and prevents all motion of the lower-jaw. In weakly and cachectic subjects the parietes of the meatus present an œdematous swelling, and there sets in an obstinate mucous discharge. The discharge is somewhat thick, almost without odour, flows not constantly or equally profuse, but varies with respect to quantity. In damp or wet weather, and when the patients catch cold, the quantity is most considerable; when the atmosphere is dry and warm it is, on the contrary, very small. If the otorrhœa is of long duration, polypus growths may form. In case of frequent returns of the inflammation varicose vessels become developed on the membrana tympani, the membrane itself becomes turbid, assumes a dappled or spotted appearance, becomes thickened, and exhibits the look of a bit of patch-work. When gouty inflammation seizes on the middle ear, it is not rarely the reflection of an arthritic angina. If it have only a short course, and the inflammatory irritation is but small, the patient complains merely of dull pinching, and lacerating pains of the ear, which become exacerbated in cold and damp weather, and diminish in severity when the atmosphere is dry; he complains also of a sense of fulness and tension in the ear; of a buzzing, singing, and tinnitus in the ear, of indistinctness of hearing, and burning pain and dryness of the fauces. The Eustachian tube is commonly open, still air when pressed in enters only with some difficulty. If the inflammation rises to a higher degree, it commences

with febrile symptoms, violent shivering, followed by heat and violent headache. Soon after an almost insupportable tearing, squeezing, and boring pain shows itself in the interior of the ear, which extends to all the affected side of the head, to the face, the teeth, to the gums and the throat, and becomes extraordinarily increased on speaking and swallowing. It continues a considerable time, returns after short intervals of rest, and has attained its acme by evening, so that sometimes loss of consciousness, rambling speech, and even convulsions, are observed to take place. During this the patient complains of increased sensitiveness to every thing which emits a sound or a noise from it, and of loud ringing, knocking, and buzzing in the ear, which shoot up his head as it were, and render his state almost insupportable. Sometimes the symptoms suddenly abate, if the paroxysm of gout shows itself in other parts of the body.

I recently saw a case where the ear affection disappeared rapidly after pains which showed themselves first in the shoulder, then in the loins, next in the knee, and lastly in the big toe. But when the inflammation attains its height, suppuration comes on; the pus breaks through the membrana tympani, and with the escape of the same outwards the disturbing symptoms gradually disappear. The pain now becomes more obtuse and heavy; it is not so extended; it is confined more to the ear and jaws, and returns at longer intervals. The purulent discharge, however profuse it may have been, diminishes; and if the disease get better, the function returns. The tinnitus aurium and hardness of hearing continue longest. As however the ear continues for a long time sensitive to every alternation of temperature, the inflammatory symptoms also sometimes return, and a state of blenorrhœa of the cavity of the tympanum with its appendages becomes established. In some cases it comes in these parts even to effusion of plastic lymph, and even to caries. If the inflammation had a more sub-acute or chronic course it may happen that chalk-like concretions form in the cavity of the tympanum, and in the mastoid process, which are naturally connected with deafness. Dr. Garrod has frequently found the cells of the mastoid process filled with chalky concretions in these cases.

Women, after cessation of the menses, suffer with acute pains of the head and deafness, the cavity of the tympanum is filled with a hard, white, gypsum-like mass, which extends to the Eustachian tube, and holds the ossicula of the ear together. That tophi and exostosis exist in the bony parts of the middle ear, is common; and many specimens are recorded of the fact. The causes of gouty inflammation of the ear are in general the same as those of gout. To the predisposing causes belong hereditary and acquired disposition to gout, venous plethora, climacteric changes, the suppression of accustomed discharges of blood, too high living, abuse of the pleasure of the table, indigestible food, excesses of all kinds, much study, dwelling in a moist unwholesome atmosphere, great hardships. As occasional causes all those influences may act, which are capable of giving rise to inflammation of the ear in general, but most frequently very rapid alternations of temperature, draughts of air, cold to the head and feet, and excessive drinking of spirituous and strong liquors. Sometimes the inflammation is also the product of metastasis, whilst some gouty attack in the head, in the hands, in the feet, in the hip, &c., suddenly disappears, and thereupon the entire process becomes developed in the organ of hearing.

2, Soho Square.

Provincial Medical & Surgical Journal.

WEDNESDAY, FEBRUARY 19, 1851.

Our anticipations with respect to the attempts which would be made by certain naval "Jacks in office," to neutralize the good intentions of the Admiralty towards the Assistant-surgeon, have been but too speedily realized. It appears from a letter to one of the daily papers, that in the fitting out of the *Indefatigable*, ample cabin accommodation had been provided for two Assistant-surgeons, and the navy authorities no doubt fully believed that these gentlemen would have sailed with every advantage which their position required. Not so, however. In the sapient imagination of the Captain, the purveyor of grog and biscuits is a functionary of far more importance than the superintendent of the health of his crew, and he therefore coolly dismisses the Assistant-surgeon to the intellectual purlieus of the cockpit, and appropriates the cabin to his own and the ship's steward. This "*Smart*" transaction has very properly called forth a severe animadversion from Mr. Browne, a gentleman whose name is identified with the movement for the enfranchisement of the Assistant-surgeon, and we trust his spirited letter may not fail to induce the Admiralty to see that their well-intentioned concessions are not in future nullified by the impertinence of the ship's captains

In connection with this subject we are induced to allude to an occurrence which has been severely commented upon in one of our contemporaries—namely, the resignation of two Naval Assistant-surgeons, when ordered to Jamaica to take charge of cholera patients. Although the last to screen any man from the odium which should always attach to the dereliction of duty simply because that duty is accompanied by personal risk, we must nevertheless think it hard

that two surgeons should meet with exclusive condemnation, when the fault committed by them, or what is tantamount to it—the exchange of commissions—is an every-day occurrence when a particular regiment is ordered for foreign service. But we are unwilling to believe that a personal fear had anything to do with the resignation in question. It is too repugnant to the spirit by which we are proud to acknowledge our profession is always animated, to conceive for a moment that apprehension of individual danger would interfere with the duties attaching to the cure of disease. The ardour with which medical men have always confronted the deadliest pestilences of modern times, forbids such an admission. It is far more probable, that these gentlemen were not altogether insensible to the degrading treatment to which their class had always been subjected, and that when it became a question whether they should expose themselves to toil and pestilence, not only without increased pay, but with no prospect of promotion, the disgust with the service, which had long been felt, then came uppermost in their minds, and that they took that opportunity, not of shunning danger, but of disconnecting themselves from a position unsuited to the feelings of an educated gentleman. So far from blaming the individuals in question, for their resignation, if this were their motive, we should like to see their example followed by others: a few such occurrences would, we think, go far to bring Government officials to a proper sense of what they must effect in the way of reformation, if they would have the important office of Assistant-surgeon in the navy filled by trustworthy men.

Of all the classes in Her Majesty's dominions, whose tempers are tried, and whose poor exchequer is diminished by the income tax, surely none is so hard hit by it as the medical profession. Supposed to be a gentleman, and constrained, therefore, to maintain an appearance upon, generally speaking, a most scanty income, the medical practitioner affords so striking an example of the hardships inflicted by that most odious tax, that even the *Times* thinks fit to take him as the most apt illustration, in a leading article which we print at a further page. We do not notice this to descant upon the iniquity of the income tax—the unfairness of taxing £500 a year derived from the most self-denying toil, as highly as the same sum coming in from funded property, and so on—but we do so to protest against the tone in which this writer thinks fit to speak of our profession. It was surely possible to exhibit the injurious pressure of the tax upon the hard-working country surgeon, without calling him "Mr. Camomile," and his domicile "Opodeldoc Lodge." Neither was there any necessity for alluding to "bergamy pitch," nor for designating an important part of his avocation as "pill-rolling." This may be wit in Printing-House Square, but elsewhere it may chance to be considered egregiously bad taste. We shall always feel grateful to the conductors of the daily press, when they lend their powerful aid to the furtherance of the interest of the medical profession, but we would inform them that their co-operation will be doubly appreciated when it is not marred by the expression of insulting superciliousness.

Proceedings of Societies.

THE BRISTOL ROYAL INFIRMARY MEDICAL SOCIETY.

This Society has been lately formed by several of the students of the above institution, with the view of advancing the professional acquirements of its members, and of promoting a feeling of friendship and co-operation amongst them, by meeting occasionally for the purpose of reading papers on any subject connected with medicine or surgery, and their subsequent discussion. The physicians and surgeons of the hospital act as patrons, whilst the office of president is filled by the house-surgeon. The introductory meeting took place on Thursday, January 9th, at which Dr. Wallis, one of the patrons, and Senior-Physician to the Infirmary, read an Introductory Address. The following is a brief abstract of the proceedings of the meeting, which took place in the Board Room at the Infirmary, where there was a good attendance of students—past and present—as well as several medical men resident in the city of Bristol.

The President opened the meeting by stating that it had long been the wish of many students that such a Society should be instituted in connexion with the Bristol Royal Infirmary, but various circumstances had occurred to prevent its formation until the present time. It had been formed on the model of the Medical Society of King's College, London, a Society which had been in existence seventeen years, and from whose ranks many men of the highest order of talent had sprung. He would not detain the meeting longer, but would call on the Secretary to read the laws of the Society,

which having been done, the President begged to introduce Dr. Wallis to the meeting.

Dr. WALLIS, who on rising was greeted with much cheering, said:—Every step which is taken to promote knowledge, is a benefit to society generally, but in no science is the welfare of the public so much concerned as in that which belongs to the healing art. This advancement of science is not so much to the profit of the medical man as to the public generally; they reap the benefit of it, and it is to promote an increase of power by which life and health may be more effectually protected, that medical science is so ardently cultivated by its professors and practitioners; and there is no means so powerful for sharpening the penetrating power of the intellect, as that of discussing scientific questions in societies like this. There is the touch-stone of a man's acquirements, loose suppositions will avail nothing here, an erroneous opinion is pinned to a man's back, and is picked at first by one and then by another, until the utterer shrink from his assailants, and is glad to hide his diminished head by retiring from the field. Reading societies connected with large institutions like these, where materials for knowledge lie scattered profusely around you, are of incalculable benefit to the rising youth who are destined to be important actors in the drama of human life; the part you will have to perform is often one of deep tragedy, and justice sternly demands your perfect acquaintance with what you have undertaken to perform. Our profession is the labour of the intellect, and not of mere muscular or brute power. Intellect, however, is a corporeal or material function; it is the act of the material substance of the brain, and like all other corporeal or muscular actions, becomes more quick and perfect by exercise and training, and this society which you have so wisely established, will be a most valuable means of giving acuteness and vigour to your growing mental energies, by affording to them a battle-field on which you may try and exercise your powers. Having made this statement of the materiality of the intellect or mind, a word or two of explanation becomes necessary, lest I should be misunderstood. When you have made yourselves intimately acquainted with the physiology of the brain, and the effects of injuries and diseases of that organ on the mind, you will I am sure totally disregard the fanciful speculation of the philosophers and metaphysicians of the old school, such as Locke, Paley, &c. I reject their doctrines altogether, as having no foundation in truth, and I am justified in doing so by a correct reading of the Holy Scripture, given to me by the late celebrated Dr. Adam Clarke, who, in a discussion on the subject, agreed with me fully, and said that the Mosaic account of the formation of man, rendered literally from the original Hebrew, was:—"And God made man, and breathed into him the breath of *lives*," and not *life*, as in our translation, thus giving to him two distinct principles, the living principle, as an animal, and an immortal principle, to be made responsible in a future state, for the acts of that order of intellect with which man is endowed higher than he has thought fit to bestow upon animals; and for this purpose he has given to man, a larger, more complete, and perfect brain, for the purpose of producing that higher order of intelligence. Gentlemen, I have a full confidence in the existence of an immortal principle and its future responsibilities, but still I am bound to confess myself a materialist as far as regards mind or intellect. Having said as much as I hope will satisfactorily prove to you that intellect is a function of the brain, and this being a corporeal organ, its activity and power can be largely extended by constant exercise, and rendered more acute and powerful by those contests of intellect which it is the prominent object of your Society to produce. When you have stored up doctrines which you may gather from books in your minds, you must put all these doctrines to the test of practical proof by the cases you have an opportunity of seeing in this house, and if they bear the test, let them be stored up in your minds as facts for further corroboration by experience, and in your discussions of professional questions you may adduce such facts with confidence, and you will see by debate whether any new light can be thrown upon them, or whether you have misapplied what you have read. In this way your intellects will be strengthened and polished by the rubs and hits you will give one another, much like the way I have seen cannon balls perfected by putting a number of them into a large iron barrel, and turning it rapidly round, when the hammering they give each other, not only polishes them, but renders them perfectly spherical. These benefits have been found practically useful at other Societies of a like nature. The Royal Medical Society, of Edinburgh, was of great use to myself; there I not only strengthened and corrected my opinions, but formed valuable friendships, many of which have lasted to the present time. The King's College Medical Society, on the plan of which yours has been formed, has been also of great benefit, many valuable men having arisen from that. Ours may be only a minor star in respect of these, but we hope, that though small, it may still shine and become at last almost as useful to its members as either of the other societies. Hence comes the advantage of a debating society, you must prove your own opinions to be true as far as proof can be obtained, and when proof cannot be obtained directly, all must be satisfied with reasonable and fair deductions; it is the capability of some men, above others, of making accurate deductions from collateral evidence, that makes one practitioner more successful than another. The more societies like these are encouraged, the more kindly feeling is engendered amongst the members, which often begets friendships which are valuable through life. I therefore congratulate you on the formation of a Society, the benefits of which I have endeavoured to set before you, and which, I hope, will be lasting. I am the more pleased to congratulate you upon this occasion, as being an old student myself of this Infirmary, and I feel a desire to promote every thing likely to be of advantage to you in your future life to the utmost of my power. Dr. Wallis then sat down amidst the cheering of those who heard him.

Mr. ROSSITER moved, and Mr. Powell seconded, a vote of thanks to Dr. Wallis for the kindness with which he had delivered his excellent address. A vote of thanks was then moved, and seconded by Mr. SWETE and Mr. CRISP, to the Medical and Surgical Staff of the Infirmary for their kindness in consenting to act as patrons.

Mr. Green, in an interesting speech, assured the meeting that no effort of the patrons should be wanting to uphold their newly-formed Society. He himself had seen the value of looking deeply into cases, and comparing the precepts of books with the practice of the wards; he should strongly recommend all students present to join the Society.

After a few words from the President relative to the working of the Society, the meeting separated.

At the close of the meeting, several gentlemen entered their names to be ballotted for as members.

E. H. SWETE, Hon. Sec.

Bristol Royal Infirmary,

BIRMINGHAM PATHOLOGICAL SOCIETY.

May 2nd, 1850.

Large deposit of Caseous Matter around the Neck of the Femur.—By Mr. Pemberton.

The *right femur* was diseased by a copious deposit of cheesy matter in the fibrous tissue around the neck, forming a large mass of diseased structure. The osseous material of the neck was nearly absorbed; the opposite femur was healthy. The *right kidney* was twice its natural size; the upper two-thirds were occupied by a deposit resembling tubercle. The left kidney was pale, and slightly granular externally. The coats of the bladder were thickened. *Lungs:* The *right* was congested, it broke down under the finger; the *left* had a gangrenous odour, and was rotten in its lower portions, and contained in its middle, cavities from broken down tissue. The *brain* was softer than natural.

The patient was a tool-maker, aged 56. He was steady, sober, and always healthy. Six months before his death the right hip was severely injured by a fall; he was confined by the accident, but no diagnosis of the injury could be formed. A month after, whilst he was standing upright by his bed, the neck of the femur gave way spontaneously. He became cachectic and debilitated. Large bed-sores formed, and diarrhœa preceded his death. His surface had assumed the tinge of malignant disease.

June 6th, 1850.

A very fine specimen of Fibrous Tumours of the Uterus. By Dr. Russell.

The fibrous tumours were embedded in the wall of the uterus, in number they exceeded twenty; they formed together a large irregular mass, quite unadherent, eight inches long and seven broad. The cervix uteri was exceedingly elongated, and projected from about the middle of the anterior face. A single large oval tumour formed the lower and narrower part of the mass, lying below the uterus, and occupying the true pelvis. The upper and larger portion of the mass was subdivided into two lateral halves by the enlarged uterus, which was completely flattened, so as to form a thick vertical partition. On its left was one large tumour; on its right were three or four considerable ones, closely connected into a group. The cavity of the uterus was much enlarged, but quite closed by the lateral pressure of the tumours. The group of tumours on the right of the uterus formed a rounded eminence in its interior, even indenting the opposite wall; this eminence was covered with a large recent clot, which ran down through the neck of the organ. The length of the flattened uterus was above five inches. The elongated neck had been divided by mistake. All the tumours were enveloped by a prolongation from the uterine tissue, from which they could be readily separated. There were also more than sixteen smaller tumours, from the size of a pea to that of a walnut, either embedded in the uterine coverings, or projecting, like nodules, from the outside of the mass.

By the microscope.—The tissue was composed of flattened bands, crossing each other very irregularly. They presented distinct though delicate fibrillation, but no separation into fibrils at the extremities, and became very transparent by acetic acid.

The patient's age was 46. She was unmarried. The symptoms were of eight years' standing, commencing with pain in the uterine region, and hæmorrhage per vaginam. The tumour was discovered four years from the commencement of the symptoms. She became subject to hæmorrhage of somewhat periodical character, which gave her a permanently bleached and cachectic appearance. She died in a sudden attack of convulsions. The head was not allowed to be opened. The os uteri could never be felt by vaginal examination.

Miliary Tubercles and Cavities in the Lungs.—By Dr. Russell.

The left lung was filled with miliary tubercles, in groups, which had coalesced towards the apex. There was an irregular cavity in the apex, and a second lower down, posteriorly. The general tissue was dense and non-crepitant. The base was congested. The base alone floated in water. Similar tubercles existed in the upper lobe of the right lung, with a small cavity, and also grey granulations throughout the middle and lower lobes. The tissue of a mottled grey. The left lung was covered universally by a dense false membrane, like a fascia. The right was clear and polished, with a slight adhesion at its apex. The bronchi and pulmonary arteries were healthy. Some scattered ulcers were in the cæcum and the colon. The liver and kidneys were free from fat in their cells.

The patient was a stone-mason, aged 36. His illness was of two years' duration; it followed upon exposure to the weather, privations, and intemperance through the winter. He was then laid by with cough, and remained subject to cough and short breath, which increased, and prevented him from working for the last fifteen months. He had pleuritic pains severely, most profuse perspiration by night and sometimes by day, and abundant expectoration of tenacious clear mucus. He decayed gradually, but his death was hastened by

diarrhœa for the last three weeks. His family are healthy.

Fœtal Heart Malformed.—By Dr. Fletcher.

The child was three weeks old. The pulmonary artery was continued into the descending aorta, by means of the ductus arteriosus, which thus conveyed the blood from the dilated right side of the heart to the trunk and lower parts of the body; these parts were more blue than the head and upper extremities, which were supplied from a *contracted* left side of the heart, by a *small* aorta, terminating in the usual branches of the arch, and in a small trunk communicating with the large descending portion.

July 4th, 1850.

DR. ELKINGTON IN THE CHAIR.

Tubercular Ulceration of the Lungs and Intestines.—By Dr. Bell Fletcher.

The intestines were ulcerated; portions of the mesenteric glands also very much enlarged by tubercular deposit; the kidneys were granular; the liver was enlarged and fatty; the body extremely emaciated. The patient was a screw-maker, and aged 70. He had hectic fever, obstinate diarrhœa, albuminuria, and anasarca of the lower extremities.

Uterus after Delivery and Diseased Heart.—By Dr. Fletcher.

The patient had been delivered fifteen days. The uterus was in the usual state; the heart was diseased, and the mitral valve considerably contracted; the left auricle was much dilated; the lungs were intensely engorged; the tubes were filled with mucus, and there was fluid in each pleura. There was general anasarca and ascites. The other organs were healthy. The patient died of intense general bronchitis, occurring in the last stage of pregnancy. She was delivered after a protracted labour, the child dead. She died fifteen days after delivery. She had long suffered from bronchitis.

Rupture of the Heart.—By Mr. Humphry.

The heart is large and weighs ten ounces. There was much fat on its outer surface; the tissue pale and soft. There was a fissure in the wall of the left ventricle five-eighths of an inch long, at the apex, and near to the posterior surface; the tissue around was almost pulpy and many hæmorrhagic spots existed in the fat of the apex. The pericardium contained twelve ounces of blood. The patient was a female, aged 87, she was in good health, became suddenly pale, and died in an hour.

Diseased Heart; Miliary Tubercles.—By Dr. Fletcher.

The mitral and aortic valves were thickened and contracted; the left auricle was dilated to about double its size; the right lung was greatly condensed; the left was partially so; there were some miliary tubercles in the right lung. The patient was subject to rheumatism, and had troublesome cough, together with frequent hæmoptysis. He died from severe inflammation of the right lung. There were no sounds indicative of the valvular disease.

Tumour around the Pylorus and Duodenum containing Pus.—By Mr. Savage, Westbromwich.

There was a large firm tumour, containing pus, surrounding the pylorus and duodenum; the liver contained some tubercles; the right kidney was enlarged; but the other abdominal viscera were healthy The patient was a forge smith aged 70; he was healthy though subject to indigestion for the last year. Seven months before his death he was attacked with diarrhœa, which continued throughout, with intervals of relief from various remedies; sweating came on and he gradually became emaciated. A tumour was discovered two months before death, which at first was rather tender, but increased and became softer. The last seven days he voided twice per anum a little pus mixed with blood.

August 1st, 1850.

MR. RUSSELL IN THE CHAIR.

Extensive Tubercular Deposit on the Pleura and Peritoneum.—By Dr. Fletcher.

The right pleura was filled with *bloody* fluid, rendering the abdominal surface of the diaphragm convex, and forcing the lung upwards; its parietal portion was studded with tubercles and with deposits of blood and fibrin. There were some elongated adhesions on both sides of the chest, but the left pleura and both the lungs were quite healthy. The pericardium contained three ounces of bloody fluid like that in the pleura, which apparently, was free from fibrin. The heart was healthy. The peritoneum contained eight or ten quarts of *bloody* fluid, it was studded with tubercles; the parietal portion was covered with fibrin entangling coagula. The omentum was nearly obliterated. The peritoneum was much thickened over the liver and gall-bladder, contracting the latter greatly. The gastric and intestinal mucous membranes were inflamed and softened. The pelvis of both kidneys and the ureters were dilated; the bladder was thickened and dilated. The left tunica vaginalis contained half a pint of muddy serum. The patient was 70, he was strong and healthy all his life, but for the last two years his habits were completely changed, by his being suddenly raised from indigence to wealth. Three months before his death ascites was first discovered, having been preceded by jaundice, which had quite subsided but was followed by emaciation. In a month paracentesis was urgently required, and three gallons of fluid containing about one quarter of blood, deprived of its fibrin, with compound exudation corpuscles, were taken. In six weeks the operation was again as urgently required, but less fluid was taken than before from an accident occurring, and the right chest remained obscured by the continued elevation of the liver. The second liver contained a little fibrin. He died a fort-

night afterwards. His mother and two sisters had malignant disease.

Malignant Tumour of the Thumb: Amputation.—By Mr. Pemberton.

The malignant tumour presented the character of soft scirrhus, springing from the periosteum of the proximal phalanx of the left thumb; the bone was equally atrophied all round, apparently by pressure, but together with the skin and extensor tendon, was quite unconnected with the disease, and was healthy. The patient was a woman aged 60. The tumour originated in a blow received four years previously. The pain at last required amputation.

Very copious deposit of Calcareous Matter in the Mitral and Aortic Valves: great enlargement of the Heart.—By Dr. Russell.

The heart was dilated and hypertrophied on the left side to a great extent; in both ventricle and auricle an enormous deposit of calcareous deposit had taken place on the free edge of both flaps of the mitral valves; it had collected in great quantity at the posterior junction of the flaps, where it had ulcerated into the auricle, just by the side of the ventricular opening. There was also a large deposit on two of the aortic valves, with ulceration, extending into the insertion of the valve of Lieutand, and causing ulceration there. The flaps of the valves and the chordæ were hypertrophied, but healthy. The external surface of the heart was dimmed by very scanty lymph. The arch of the aorta was nearly free from atheroma. The lungs were healthy. The patient was a man aged 42. He was subject to symptoms of heart disease, frequently urgent, for at least twelve years. They were kept in abeyance by quietness and regular living, though progress in the disease was indicated from time to time. Seven months before death he had an attack of bronchitis, and his symptoms from that time advanced rapidly. He had anasarca, but no ascites; and there was jugular pulsation. He died very suddenly. He never had rheumatism.

Large Calcareous Excrescences from the Aortic and Mitral Valves: Enlarged Heart.—By Dr. Nelson.

Presented by Dr. Russell.

The heart was dilated and hypertrophied to a great extent on the left side, its weight was one pound three ounces. A large cauliflower-like excrescence of calcareous matter was connected with one of the aortic valves, and hung into the ventricle; the two other segments of the valve were nearly destroyed by the breaking down of the deposit between their laminæ. Other smaller excrescences adhered to the base of the mitral valve and to the valve itself. The right valves were healthy. The pericardium was healthy. A calcareous deposit was in the apex of the right lung. The patient was a male, aged 23. Had symptoms of his disease for ten months before death. He never had rheumatism. Anasarca came on with great dyspnœa and violent action of the heart; and he had also troublesome wakefulness. His urine was free from albumen.

Very large Tumour in the Anterior Mediastinum firmly attached to the Pericardium; Effusion of Blood into the Brain.—By Dr. Nelson.

The following case was presented through Dr. Russell:—

There was a *large tumour in the anterior mediastinum*, lying in front of the pericardium, and intimately connected with it; it extended from the entrance of the great vessels into the neck down to the diaphragm, to which it adhered, and on each side it was of equal extent with the costal cartilages. The general appearance of the growth was just that of the thymus gland; its tissue under the microscope had a simply granular appearance. The heart and great vessels were healthy, as was the pericardium. The left kidney was large, pale, and its structure not distinct. The brain was congested. The optic thalami and corpora striata were broken down by a recent clot, which contained some pus corpuscles; it weighed two ounces, and occupied chiefly the anterior cornu of the lateral ventricles. The bones of the hip-joint were diseased, the ligaments degenerated, and the head of the femur thrown on the dorsum ilii. The patient was a boy, aged 17. He had been somewhat out of health for two years, with pain in his head and right side. He was pale and puffy, but had no symptoms to direct attention to his chest. His urine was free from albumen. He had constant pain between his scapulæ, and pain and tenderness in the hepatic region; the latter complaint was removed by treatment. He suddenly became stupid, and fell into a state of coma, in which he died about sixteen hours after, with all the symptoms of compression of the brain, but without convulsions. He had long been the subject of disease.

Three specimens of Diseased Bones.—By Mr. Pemberton.

Acute Disease of the Left Hip.—The articular cartilages were destroyed, the bones were carious, the head of the femur was nearly absorbed, and there was a large opening, which would admit three fingers, through the floor of the acetabulum. The cancellated structure of the bones was soft, red, and vascular, and the cancelli were filled with cheesy matter. A large abscess, which had burst externally, communicated with the joint. The patient was a boy, aged 15, a needle-pointer. The disease was acute and rapid, extending over ten weeks only.

Scrofulous Necrosis of the Left Tibia.—The shaft of the tibia formed a large sequestrum, surrounded by a sheath of new bone, and perforated by numerous apertures. The articular extremities were still connected with the old bone, but were surrounded by the new growth. The fibula was perfectly healthy. The soft parts of the leg were perforated with numerous sinuses. The patient was a boy, aged, 14, a nailer. His disease commenced immediately after typhus, two years previously. The limb was amputated, and the patient recovered.

Anchylosis of the Ulno-humeral Articulation.—The

bones were much thickened, but the left condyle of the humerus, with the radio-humeral articulation, was quite healthy. There was a lumbar abscess, and caries of the lumbar vertebræ. The kidneys were in the first stage of Bright's disease. The patient was a girl, aged 19; she was a dressmaker. Had scrofulous disease of the elbow in early childhood. She recovered with a stiff joint, but retained the power of pronation and supination. She had albuminuria.

Foreign Department.

PROCEEDINGS OF THE FRENCH ACADEMIES.

ACADEMIE DES SCIENCES.

The following are the most interesting subjects of discussion at the late meeting of the Society:—

M. Curie endeavoured to explain the phenomena attending *sea-sickness*. "It is generally admitted," he observes, "that when the vessel descends into the trough of the sea, the moveable contents of the abdomen are projected against the diaphragm. When, on the contrary, the ship rises on the wave, a contrary movement takes place, the intestines dragging down the diaphragm. But as this muscle is the main agent in the mechanism of vomiting, in order to prevent sea-sickness some means must be found of neutralizing the effects of the ship's movements upon it." This remedy is found, according to M. Curie, in a particular management of respiration, taking care to inspire when the vessel dips, and to exspire when she lifts on the seas. This process continued at intervals he declares to be successful.

The workmen engaged in manufacturing quinine are subject to a skin disease, which has been noticed by M. Chevallier

M. Claude Bernard presented some remarks on an active poison, known as the *curare* (woorara?), which is in use among the natives inhabiting the regions of the Orenoko, Rio-negro, and Amazon rivers. It is said to be derived from a plant analogous to that which furnishes nux vomica; but it is also supposed to be a compound of the poisons of venomous snakes. It certainly has properties in common with the latter; for though deadly when inserted into the skin, it may be taken into the stomach with impunity. Its poisonous action is instantaneous when injected into the veins, but inserted under the skin, it is delayed for a few instants, according to the strength and size of the animal. In birds it destroys almost instantaneously, without pain or expression. So also in dogs which were experimented upon.

In animals thus destroyed, M. Bernard always remarked signs which were indicative of a complete paralyzing of the nerves, which immediately after death look as if the animal had been dead for many hours; the blood was always pitchy black, and did not redden on contact with the air. It was also noticed that contact of the poison with the mucous membrane produced no sensible effect upon it.

M. Demeaux mentioned the existence of peculiar albuminous granules in the seminal fluid of unprolific men. They are kidney shaped, insoluble, and become opaque on the addition of alcohol or nitric acid.

M. Claude Bernard made further remarks on a new function of the liver, that of forming sugar. This subject has been noticed in a former number of this *Journal*.

M. Coste also lectured at the present meeting on *Gestation in the Human Species*. He has had numerous opportunities of examining women during and at the close of menstruation. In all, without exception, he found the interior of the uterus lined with a membrane, so thick, that but for the constancy of its presence it might be regarded as morbid. Thus it appears that on each maturation of an ovule, the uterus prepares itself to receive it. M. Coste has also ascertained that the fallopian tubes are not closed by this adventitious membrane, but are perfectly free to allow the passage of the ovule into the cavity of the uterus. In the unimpregnated state, therefore, the ovum falling into the new membrane, becomes imbedded in it, and is then developed, pushing before it a lamina of this membrane, which becomes the decidua reflexa, while other portions become the placental layer of decidua, and the parietal or uterine layer.

On the Elastic Fibres of Phthisical Sputa.

Dr. Schroeder Van der Kolk (*Revue Médicale*) has stated that the existence of cavities in phthisis may be ascertained with certainty by the discovery of the elastic fibres of the pulmonary cells in the sputa with the aid of the microscope. These fibres are liable to be mistaken for a species of conferva which is generated in the expectoration, but the latter is distinguished by terminating in cellular enlargements.

Male Fern in Tapeworm.

The value of this medicine is corroborated by M. Martin Solon, (*Bulletin de Therapeutique.*) He gives it in powder, in the dose of ten drachms, followed by castor oil. The oil of the fern is also very efficacious, mixed with the powdered root. The expense of the kousso has induced British chemists to prepare a tincture of the root, which has been very successful in some of the London hospitals.

Treatment of Encysted Tumours by repeated Injections of Iodine.

In the *Journal de Medicine de Bruxeles* of January 1851, M. Borelli describes his method of treating encysted tumours. After piercing the cyst with a lancet, and evacuating its contents, a saturated solution of iodine is injected, and retained by closing the external wound with diachylon; over this a poultice is

placed as soon as inflammatory symptoms arise. The tumour soon softens and collapses, and the pus mixed with the adventitious fluid escaping at the same time. After one or two injections the vitality of the cyst is destroyed, and it may be drawn out with pincers. This proceeding is quickly followed by a radical cure.

General Retrospect.

ANATOMY AND PHYSIOLOGY.

On the Round Ligament of the Uterus.

By G. Rainey, Esq.

Speaking of the difference between the striated and non-striated varieties of muscular fibre, Mr. Rainey denies that the round ligaments are composed of the latter; and affirms, on the contrary, that they are composed of the striated or voluntary fibre. This opinion he supports on the following grounds:—first, that the round ligament arises from three tendinous and muscular fasciculi; one from the tendon of the internal oblique, a centre one from the upper column of the external abdominal ring, the third from the inferior column of the same. These uniting form a round end, which expands upon the angle of the uterus. The striped fibres chiefly occupy the centre of the cord, but as they approach the uterus they lose this character, and assume that of the dartos muscle.

Mr. Rainey further states that the round ligaments do not, as was supposed, emerge from the external ring to be inserted upon the mons veneris; and that their use is in some manner connected with the act of coition.

In the same essay the author investigates the changes which the uterus undergoes during gestation. He regards the increase in size to depend upon the development of the embryonic nucleated fibres of the unimpregnated uterus, which receive a new impulse on the reception of the ovum. After parturition he supposes the fully developed fibres to be absorbed and replaced by fresh embryonic ones.—*Philosophical Transactions.*

PRACTICAL MEDICINE AND PATHOLOGY.

On a Functional Affection of the Spine which may be mistaken for Organic Disease.

By Henry Kennedy, A.B., &c.

The affection to which Dr. Kennedy alludes is essentially a disease of early life, generally occurring between the ages of twelve and twenty. It is more common in males than in females. It consists in a pain in the back and loins, commencing gradually, and may or may not be attended with the feeling of weakness, and occasionally it is only the latter that is complained of. The patients will say that if they have occasion to stoop—as, for instance, to tie their shoe—the rising up gives the feeling as if the back would break. When we come to examine the spine, the patient is nearly always able to refer the suffering to a particular part, but Dr. K. has seen cases where they could not do so, the feeling being then more diffused; and it is particularly worthy of notice, that a rough examination of the part may be made—the spine may be twisted, or percussion strongly used, and yet the patient will not complain of it. When left to their own feelings, they invariably prefer the recumbent posture. Walking is much less irksome than sitting, and particularly when they have no support for the back. In addition to an ordinary chair, they will use a cushion, so as that it may press on the spine where they complain; and even when reclining at full length, it is not uncommon to see a cushion placed in the hollow of the back, and in this way to cause direct pressure, in fact the feeling of support is one they cannot do without, and they will use many devices to attain it. Those whose business leads them to stand and work at a desk, seem peculiarly liable to the affection.

The following case illustrates the affection:—Mr. ———, a young gentleman of 18, whose employment was in an office in Dublin, where he spent six to seven hours a-day, partly standing and partly sitting, at a desk, began to suffer from pain in the small of the back. He was a person of small size, but of a highly-developed nervous system, as was shown when he laboured under any common indisposition—as, for instance, a cold. The pain in the back was trifling at first, though constant, so that he was able to pursue his usual avocations for about four months, when it became so distressing that he was compelled to confine himself to a sofa the greater portion of the day, and when he did sit up he always used a cushion between his back and the chair. On examination nothing wrong could be detected with the part of the spine of which he complained most, which was about the third lumbar vertebra; it could be twisted, and otherwise roughly handled, without causing any inconvenience, but to sit without support could not be endured beyond a few moments. And it is particularly to be observed, that when he had any inducement, he could go through an amount of exertion on his feet, which seemed totally incompatible with the other symptoms present. His general health appeared good, his tongue clean, his appetite not impaired, and, in fact, except for the complaint of the back, he was otherwise well.

He continued in this state for four months, during which time he was seen by the late Mr. Carmichael, and a variety of treatment was adopted, but no means used were of decisive benefit. In two months more he had recovered so far as to be able to resume his business, and at a still later period recovered completely; nor has he ever since, though some years have passed, suffered from the same affection.

On the subject of treatment the author has nothing of a very definite nature to offer. A considerable variety of means have been used, of both a local and constitutional kind. The former included local bleedings, dry cupping, blisters, frictions, the cold douche, and galvanism; and the latter aperients, tonics, change of air, and relaxation from business. Of these two,

the latter have, in his experience proved by much the most useful. He has also seen benefit follow the application of small and repeated blisters, as also the use of a weak stream of galvanism, applied daily, or every second day, according to circumstances. The patient, too, has often got great relief from wearing a stiff belt; indeed, this is a measure which should not, in any case, be forgotten. Still the general measures are the more important. In all the severer cases the patient will have to give up his business for a time; two to three months' complete relaxation must be enjoined, and if the patient can change his air so much the better.—*Dublin Medical Press.*

SURGERY.

Compound comminuted Fracture of the Femur; Separation of the Patella, and a large portion of the lower end of the femur; Recovery.

A hawker, aged 36, was admitted sometime back under the care of Mr. Luke, having sustained a fracture of the ilium, which united in about six or seven weeks. On examining the right lower extremity, the effects of an old accident were evident,—the limb was shorter than the left by two and a half inches, its axis directed downwards and somewhat forwards and outwards, the leg being, in relation with the thigh, at an angle of 130°. There was imperfect anchylosis, and the knee-joint admitted of slight flexion and extension. A large depressed cicatrix existed at the lower and inner part of the thigh, oblique in direction, and six inches in length. The most depressed part of the scar was bounded below by the prominent inner part of the circumference of the head of the tibia, which had been drawn considerably upwards, to the extent, in fact, of about two inches beyond the level of the other, and occupying the place of the inner condyle of the femur. No trace of the patella could be detected, but the anterior and outer part of the head of the tibia was bounded by a prominence of bone broader below than above, continuous with the shaft of the femur, and evidently its modified external condyle. The measurement round the circumference of the right leg, (which presented at its upper and outer part the continuation of the cicatrix observed at the lower part of the thigh,) at its upper third, was ten inches; the measurement round the unaffected limb, in the same situation, being thirteen. The measurement round the upper part of the affected thigh was sixteen and a half inches; of the left, eighteen inches.

The patient stated, that when he was 18 years old he was pitched out of a loaded cart, and the wheel ran over the knee and leg. The injury was of that severe character that the medical man who was called in urged the propriety of the removal of the limb. The patient, however, would not consent, and his mother treated the limb herself; poultices of various kinds being had recourse to. After he had lain a long time in bed, he pulled away several loose pieces of bone from the lower and inner part of the thigh, and ultimately the knee cap. In two years after the accident he was able to walk to school on a short crutch, and ultimately got so far well, "that he could walk, was able to wheel a barrow, and do many pieces of laborious work; and, having to cut grass about hedges or among trees, got expert, and every harvest had to work."—*Medical Times*, December 7, 1850.

Treatment of Internal Hæmorrhoids.—By Dr. Garvin.

Dr. I. P. Garvin, in an interesting article in the *Southern Medical and Surgical Journal*, states that he has treated a considerable number of cases of internal hæmorrhoids, some of them very severe and of long standing, by the use of cold water, in the following manner:—He directs about a gill of cold water to be thrown into the rectum immediately before *every attempt* to evacuate the bowels, and that this enema be retained several minutes, if possible. This usually produces an evacuation of the fæces, which have been so far softened on their surface as to permit their escape without the least straining or irritation. After every evacuation it will be proper to use ablutions of the parts, more especially in such cases as are attended by some protrusion of the bowels. The treatment is to be continued until some days after all uneasiness is removed. In old or very severe cases, to effect such amendment generally requires several weeks. It is highly important to impress upon the patient the absolute necessity of perseverance in the use of cold water, even though he should be so far relieved as to feel *almost* well, for if it be suspended too soon, a very slight cause will bring on a relapse. So decided is the relief afforded, by this treatment, that few persons would be disposed hastily to abandon it, but for the inconvenience of applying it daily. The ordinary apparatus for enemata are so unwieldly, that they cannot be carried about conveniently. All difficulty from this source may be obviated by the employment of a small pewter syringe, with a ring handle to the piston. One which will hold two ounces is very convenient, and may be carried in the pocket when necessary. When such enemata of cold water fail to procure sufficient alvine evacuations, the quantity of fluid may be increased to half a pint, or it may be necessary to resort to mild laxatives. Active purgation must be carefully avoided. The patient should be advised never to aid the natural expulsive action of the bowels by straining.—*Amer. Journ. of Med. Science*, and *Dublin Medical Press.*

MIDWIFERY AND DISEASES OF WOMEN.

Treatment of Infantile Convulsions.

By Dr. Schopferei.

During the paroxysm medicine can do but little In general harm is done by hasty interference. Many practitioners no sooner have a case of convulsions than they apply leeches. The author thinks that in most cases they are useless or pernicious. He opposes the indiscriminate theory of congestion.

During the fit, if the child be weakly and anæmic, he orders the head to be inclined downwards; if, on the

contrary, it is robust, the head should be elevated. He also strongly advises enemata, sometimes simple, at others containing infusion of camomile or valerian. In weak infants he has seen much benefit from compressing the vessels of the thighs.

Leeches are indicated when the child is robust, and when in a strong child the fit continues in spite of a lavement. If there be evidence of dental irritation, no time should be lost in scarifying the gums.

When the fit is over, the subsequent treatment will be regulated accordingly as the disease is idiopathic or symptomatic. In feeble children a tonic and nutritious regimen is required. In some iron is indicated, and cod-liver oil is beneficial in giving an impulse to nutrition. Cold affusion and exposure to a dry bracing air are very important adjuvants in the treatment.

The author objects to the free use of mercurials which is so commonly resorted to in this country.

In chorea he places greater faith in cuprum ammoniatum than in any other medicine.—Translated in *Edin. Month. Journ.*, December, 1850.

CONVENTION OF POOR LAW MEDICAL OFFICERS.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—I am desired by the Committee to forward to you the accompanying report of an interview with Lord John Russell, on Friday last, relative to an improved system of Poor-Law Medical Relief; and to request of you the favour to publish it in the next number of the *Journal*.

I am, Sir, your obedient servamt,

HERBERT WILLIAMS,

4, Hanover Street, Feb. 4th, 1851. Assistant Secretary.

REPORT OF THE INTERVIEW WITH LORD JOHN RUSSELL.

On Friday week a deputation from the Convention of the Poor Law Medical Officers had an interview with Lord John Russell, with reference to the evils of the present system of medical relief to the sick poor, at which Sir George Grey was present.

The deputation, which was accompanied by General Sir De Lacy Evans, M.P.; Jacob Bell, Esq., M.P.; Dr. Wilson, Senior Physician of St. George's Hospital; Thomas Hunt, Esq., representative of the Provincial Medical Association; James Stedman, Esq., Vice-President of the National Institute of Medicine, Surgery, and Midwifery;—consisted of Dr. Hodgkin, the Chairman of the Committee; Dr. Bainbridge, Messrs. W. Lobb, J. Liddle, E. White, W. Cantrell, of Wirksworth, Derby; Peter Martin, Reigate; E. Boulger, Bletchingly; G. Ross, J. T. Mitchell, Dr. Barnett, and Charles F. J. Lord, the Honorary Secretary.

The deputation having been introduced by the Chairman, the Honorary Secretary stated, before reading the memorial, that M. Foster, Esq., M.P., H. A. Aglionby, Esq., M.P., Thomas Wakley, Esq., M.P., J. Wyld, Esq., M.P., and several others members of Parliament, had expressed a desire to join the deputation. Delegates from the Medico-Ethical Society of Liverpool, and other Associations, had also expressed a similar wish, but unexpected engagements and the shortness of the notice, rendered their absence unavoidable. It was further stated that a movement of a similar character to that which originated this deputation, was becoming active in Ireland, and that a large meeting had just been held on the subject in Belfast.

The memorial set forth the evils of the present system, and showed that the three thousand poor-law medical officers, who administered relief to nearly three millions of the suffering poor in England and Wales, were so inefficiently paid, that the cost of drugs alone was, in many cases, barely met by the salary. The average rate of payment for each case of sickness, as ascertained from 805 returns from Officers of Unions, is 1s. 6¾d. for metropolitan districts, and 2s. 7d. for country districts; whereas the cost of drugs for dispensary cases, amounts to 2s. 1½d., and for hospital cases 4s. 4½d. It further stated, that the burthens which have been imposed on union surgeons, through the regulations of the General Board of Health, under orders from the Poor-Law Board and Guardians, while no provision existed to secure extra payment for these important services, were of a distinct character from those imposed on them by their contracts with the Board of Guardians. In illustration of the evils of the present system, special allusion was made to the case of "Hyet *v.* the Cheltenham Board of Guardians," in which Mr. Justice Patteson, in his address to the jury, stated that, "the medical officers of unions were the hardest worked, and worst paid class of officers in the kingdom." The memorial concluded by suggesting, for the amendment of the system, the following principles:—1st. Permanence of office during competency and good conduct. 2nd. Remuneration proportioned to the extent and nature of the duties. 3rd. Responsibility to professional authority under medical inspectors; and praying his lordship to introduce a Bill into Parliament embodying these provisions.

Mr. Boulger, of Bletchingly, represented, "that the uncertain tenure of office appeared to be greatly detrimental to the due discharge of the duties of the medical officers of the poor-law districts. The medical officers were often prevented from acting conscientiously towards their patients, through fear of incurring the displeasure of their employers, the guardians. That the medical profession was not more venal than any other body of men, and that if the appointment of a medical officer was made to endure *quamdiu se bene gesserit*, such an arrangement would redound no less to the benefit of the poor, than to the honour and advantage of the medical profession. Mr. Boulger mentioned, that in his own neighbourhood a medical officer had been removed without cause, and without a moment's notice by the guardians, who elected a person in his stead, whom they subsequently deemed inefficient. The guardians in a few months stultified themselves by re-electing their former medical officer. Such circumstances and changes must be fraught not only with discomfort, but with actual injury to the poor."

In reply to a question by Sir George Grey, Mr. Boulger apprehended that the decision as to the com-

petency or incompetency of a medical officer would rest with the proposed medical inspectors.

Mr. Cantrell, of Wirksworth, Derbyshire, stated that he represented the opinions of a great number of medical officers in Derbyshire, and had had much experience of poor-law medical practice, having been a parish surgeon before the passing of the present law, after which he acted as guardian for two years, and had ever since been a medical officer of an extensive poor-law district; that he considered the remuneration was both unequal and inadequate, and suggested that the mode of payment should be based on the population, extent, and poverty of the districts, which could be easily ascertained. He objected to a payment per case, as it would act injuriously to the poor, as disease would become fixed and death often occur, before an order would be obtained, if it involved an extra fee; to show which he stated that since he had become medical officer he had never received more than six orders to attend labours because it involved an extra fee. He also referred to the advantage of having medical inspectors.

Sir George Grey asked the deputation with whom they intended that the power of electing and appointing the medical officer should rest? Lord John Russell also desired to know whether it was proposed that the entire expense of medical relief should be discharged through the consolidated fund?

The Honorary Secretary stated, in reply to both these questions, that, as half of the expense was already paid by the Government, it was deemed desirable that the entire cost should be derived from the same source; it had been suggested, however, that the cost of drugs should be met by the poor-rates. It was proposed that the guardians should still have the power of nominating their medical officers, but that the Government should appoint the medical inspectors.

Mr. Liddle stated that he had had sixteen years' experience of the working of that part of the poor-law which related to medical relief, and he could confidently affirm that it required great alteration and amendment. He would, however, only direct his Lordship's attention to the necessity which existed for appointing medical inspectors. At present the medical officers of unions were under the entire management and control of the Boards of Guardians, to whom they had to make weekly reports, but which reports were seldom, if ever, looked at by the guardians, or if they were, the guardians could not understand them; they were, therefore useless; but if such reports were submitted to a medical inspector, much benefit would accrue, not only to the medical profession, but to the public at large, as the medical inspector would be able to make most valuable statistical returns, which would materially tend to the advancement of science, and the physical improvement of the people. The labour which was now imposed upon medical officers, in compelling them to keep useless books, was extremely onerous and burdensome. Secondly, it often happened that sanitary duties, and very properly so, were imposed upon the medical officers; but under the existing arrangement, it was impossible they could conscientiously do their duty to the public, if they were desirous of keeping their appointments, for it frequently happened that much property in poor neighbourhoods belonged to individual members of the Board of Guardians, and which was in such a bad sanitary condition that it was positively injurious to the health of the neighbourhood; but the medical officer dared not report it to the Board, for fear of losing his appointment. Thirdly, disputes often arose between the medical officer and the patient, which of course were referred to the Board of Guardians, but the guardians were altogether unable to come to a satisfactory decision upon the subject in dispute, not understanding the nature of the case. The matter was then sometimes referred to the Poor Law Board, who (from there not being a medical man in that department) were just as incompetent to form a correct judgment of the matter in dispute. For these and other reasons which might be adduced if time permitted, Mr. Liddle pressed upon the attention of Lord John Russell the advantage to be derived from assimilating the civil service in the department of medical poor-law to that of the army and navy.

Mr. Hunt, of Bedford Square, said, that he had the honour to represent the Provincial Medical and Surgical Association, consisting of about 1500 members of the profession, residing in various counties of England and Wales. This Association was accustomed to meet annually in large numbers. Many of the members were poor-law medical officers, and the subject of the medical administration of the poor-law had frequently been discussed, and after careful consideration, the Association had petitioned Parliament on the subject. In this large body of practitioners, Mr. Hunt believed there was unanimity of opinion on the subject of the memorial now presented to his Lordship, in the petition of which they cordially concurred. They especially felt the necessity of medical inspection, and the injustice of non-medical guardians deciding upon questions of medical competency and services.

Mr. Stedman, of Guildford, stated, that in his capacity of Vice-President of the National Institute of Medicine, Surgery, and Midwifery, he was constantly in the habit of hearing from the numerous members of the Institute and National Association, that one of the great grievances of the profession, was the unsatisfactory way in which the medical officers of Unions held their appointments, and the very insufficient remuneration they received from the Boards of Guardians. That a medical inspector would prove acceptable to the profession, as a medium for regulating the payments to the medical officer, and as a general referee to whom all medical questions might be referred. He also directed the attention of his lordship to the difference of the amount paid for medical attendance on prisoners, and on the poor.

Sir George Grey was under the impression that the medical officers of prisons devoted their whole time to the prisoners.

Mr. Stedman stated, that the surgeon to the Guildford House of Correction received a salary of more than double the sum given to the surgeon of the Union House, the inmates of the prison being numerically fewer, and that the gentlemen holding those appointments were both engaged in general practice.

Jacob Bell, Esq., M.P., stated, that having been many years a guardian, he could testify to the defects of the present system, one of which was the very inadequate remuneration afforded to the medical officers; another was the absence of medical authority in regulating their

duties, and supervising the whole administration of medical relief to the poor. He entirely concurred with the principles of the memorial, and was anxious to further its objects.

Dr. J. Arthur Wilson said, that although unexpectedly called on, he should have great satisfaction in supporting the memorial of the medical officers of the Unions. He was pained and surprised that nearly three thousand gentlemen of education, the physicians of the poor, for they were called on to conduct the most important cases, both in medicine and surgery, should be subjected to such treatment as was described in the memorial. He had observed, in a periodical of last week, two cases which struck him as shocking in a country like ours. At Bury, an inquest had been held on a poor man aged seventy-one, who had fractured his thigh, and who died in consequence of bed-sores, the guardians having obstinately refused to supply for his use, as requested by the medical officers, either a water-bed or one of Hooper's water-cushions. At the inquest the guardians attempted to transfer the blame to the medical officer, by alleging that the sufferer died from improper medical treatment; the jury, however by their verdict, fixed the blame of neglect and cruelty on the Board of Guardians, who ought to have supplied every applianee considered necessary by competent medical authority. After mentioning an analogous case at Southampton, Dr. Wilson went on to say, that such examples, which were unfortunately too common, proved the absolute necessity of an intermediate authority, which should possess the requisite professional knowledge to direct guardians in doubtful points respecting medical matters. Dr. Wilson in strong terms expressed his sense of the injury done to society by the occurrence of such incidents as those above related, and said that he believed the mind of the medical profession in London was aroused to the evils of the present system, and to the stigma cast upon it by the treatment to which so large a section of the profession was subjected. As Physician of an Hospital, he knew the poor, and he knew that, in sickness especially, it was unwise and ungenerous to afford them medical aid in a way which might not be agreeable to their sympathies, rendered keen under pain and affliction. After what he had heard to-day, he should advise medical pupils, of whom he had seen successive generations, to avoid contact with Boards of Guardians. They should be always ready to afford aid to the sufferer, whoever might apply; but if they valued their comfort and respectability, they must be careful how they accepted medical appointments under the Poor Law.

Sir De Lacy Evans, said, that as he was with one exception a non-professional person, he might be excused for offering a few observations to his lordship. He felt the importance of a question which involved proper medical attendance upon 3,000,000 of the poor in the hour of sickness. He first, however, wished to correct an omission in the memorial, which stated that the Poor-Law Board had only in two cases ordered a reduction of salary to the medical officer contrary and in direct opposition to the votes of the guardians; he alluded to the case of St. Martin-in-the-Fields, Westminster, as another similar instance in which the Poor-Law Board had, against repeated applications and unanimous votes of the guardians, enforced a reduction of the salary of the medical officer of the workhouse. Perhaps it might be arising from his military education, but it appeared to him a great anomaly that there should not be some reference to medical authority in this civil service (which concerned 3,000 medical gentlemen) as there was in the army and navy. It struck him also as remarkable, that there should be so great a contrast between the payments made to the medical officers of prisons and those who attended the poor. It appeared that in many instances the payment to medical officers of prisons was five, six, and seven times greater than that given to poor-law medical officers.

Sir George Grey observed, that those appointments were made by magistrates, and that the whole of the time of the officer was given to those duties. This was immediately met by several of the deputation asserting that these officers practised generally, as well as attended to the prisons.

Mr. White stated that he was a medical officer of one of the Unions alluded to, in which the Poor-Law Board had recommended a lower remuneration for services than that submitted for their confirmation by the guardians. In his Union there were three medical officers; their cases averaged 9,000 annually, for which they received £465 per anuum, or about 1s. per case; the guardians, after refusing any remuneration for attending cases of cholera in 1849, determined on adding another medical officer, although no complaint was alleged against the old ones, thus taking off one-third of their salaries, and the *four* now received £65 a year less than had been paid to the *three*. In making these remarks he wished to do justice to a large portion of the Board of Guardians, as these changes were effected by small majorities of one and two only, and a protest was entered on the minutes by the Chairman and a large number of the Board against this injustice to the medical officers. The medical officers obtained an interview with the Poor-Law Board, who, upon further consideration, recommended an increased allowance, *but still less than that first suggested by the guardians.*

Lord John Russell having courteously and attentively listened to the facts and suggestions set forth in the memorial, and to the remarks of the deputation in support of them, stated that he had had much communication with the late President of the Poor-Law Board, Mr. Charles Buller, and lately with Mr. Baines, on this subject, that the question was surrounded with difficulties, financial and otherwise: he would, however, speedily communicate with Mr. Baines with reference thereto.

The Hon. Secretary, in thanking the Premier for the lengthened audience his lordship had given to the deputation, trusted that his lordship would not allow them to depart without an assurance that the subject should meet with remedial legislation. He presumed to press this the more, as a mass of evidence in favour of such redress was collected by the Parliamentary Committee in 1844; and also, as the question had been constantly agitated by the Convention for more than three years, and furthermore, as they had been on former occasions assured by Government and the Poor-Law Board, that it should be speedily considered in relation to an amended law on the subject.

His lordship again promised that he would specially

communicate with the President of the Poor Law Board with reference to the objects sought by the deputation.

The deputation then withdrew.

BIOGRAPHICAL NOTICE OF THE LATE R. THORPE, ESQ., SURGEON.

Our last *Journal* contained a notice of the death of this eminent surgeon, which took place on Tuesday, at his residence in Piccadilly, Manchester, in the 63rd or 64th year of his age. We have sought to collect some particulars of the early life and subsequent professional career of a man who was known not only in Manchester, but throughout the kingdom, as one of the cleverest anatomists and operating surgeons the three kingdoms contained; but we have not succeeded to the extent we desired or expected.

Mr. Thorpe was the son of Mr. John Thorpe, himself an eminent surgeon, who resided in King Street for a number of years. He was educated at the Manchester Free Grammar School, when conducted by Mr. Charles Lawson, and having creditably passed through the curriculum of study then pursued there, he became a pupil with his father, and commenced that career which in future life was destined highly to distinguish him. Having passed through the usual course of instruction in London, and the ordeal of examinations in a manner that gained him many compliments, he subsequently returned to Manchester, and commenced the practice of his profession. He became connected with the Manchester Royal Infirmary in 1812, by his election on the 2nd of April in that year. We need not, in this brief memoir, refer to the very different position of that institution then and now, or to the changes which have taken place in the town since the period stated. Mr. Thorpe entered upon his office with that alacrity and energy which was always a trait in his character, and continued to perform the duties which devolved upon him with untiring assiduity until the 19th of Feb., 1849, when he resigned the office of surgeon. He was elected the same day one of the consulting-surgeons to the institution, and held that honourable position at his death, in conjunction with his old schoolfellow and attached friend through life, Mr. J. Ainsworth. Mr. Thorpe was distinguished alike for professional skill and for private worth. In respect of the former, it is scarcely possible we can say too much. Intimately acquainted with the minutest details his own researches or those of other investigators had revealed in anatomy, possessed of a ready and most accurate perception of the condition of a diseased part, he had, further, that indispensable requisite for an operating surgeon, an iron nerve and a steadiness of manipulation never exceeded. Ever careful not to inflict unnecessary pain, once assured that nothing but an operation remained, its magnitude never appalled him, nor did its momentousness cause him to falter. This decision, and strength of nerve, combined with certainty of eye and hand rendered him most successful, and spread his fame even in London. So solid was its basis, that among his professional brethren in Manchester his word had almost the authority of law, and his decision was looked for with deference. A fact we have heard illustrates this in a striking manner. At the Royal Infirmary, when an operation appears to be necessary, it becomes a matter for consultation among the medical staff before it is undertaken, and the decision depends upon the majority of votes recorded, commencing with the youngest member and ending with the senior. Mr. Thorpe could not always attend these consultations, and it has happened that a patient about whose case he had not been in consultation, when arranged on the operating table, has been removed because he (Mr. Thorpe), after examination, expressed his opinion that it would be better to wait a short time. Such a fact is perhaps the strongest proof we can cite of the deference paid to his skill by his colleagues. Of course so distinguished a man could scarcely fail, during a long professional career, to be the instructor of others; and we might easily point to surgeons in Manchester who remember their pupilage under him with feelings of great pleasure, and who acquired in that position the talent which now elevates them. In private life Mr. Thorpe was distinguished by the benevolence of his character, and by the unostentatious manner in which he distributed his ample means among those whom he believed to be requiring and deserving of aid. Little known through the medium of newspapers as a public benefactor, he was one of our most active dispensers of assistance to distress, to an extent which will never now be known. Clever and enthusiastic as he was in the pursuit of his profession, we do not hear that he published anything upon any department of medical science; and though he was possessed of literary tastes, his public appearances, as a man of letters, were very few indeed.

Correspondence.

ON MEDICAL REFORM.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—Your correspondent "L.A.C.," is in error when he states that I should be a gainer by the establishment of a new College of General Practitioners. I have passed an examination, and by the license of the Apothecaries' Company am legally entitled to practise the science of medicine.

The question, however, is one far above personal consideration. It is one upon which the permanent *status* and usefulness of a great profession depend; and, therefore, I may perhaps be excused if I state my views upon the subject more at length.

I believe the greatest error that ever was perpetrated in medical legislature was that of perpetuating, by the Act of 1815, the union of the science of medicine with a trading corporation. I do not wish to derogate from the respectability of fair and honourable barter, as it exists among the great body of tradesmen in this country; I merely assert that it cannot, without great injury, be united to a science like that of medicine. By the Act of 1815 the licence to practise the "art and mystery" of medicine could only be obtained by passing an examination before a Board selected from a trading corporation. By that Act the principle of charging for medicine was legalized; and the practice of the great body of general practitioners since that day has been to charge a certain sum for the medicines taken by their patients, by which they were remunerated for the exercise of their skill and scientific attainments.

Now, the charge for medicine is either a direct trading act, or it is a roundabout way of charging for medical attendance. In the first case, every principle which regulates barter among tradesmen is violated, inasmuch as the charge for the medicine is infinitely greater than its real value in the market. In the second case, it must be wrong in principle to charge a

person for one thing, meaning at the same time to pay yourself for another.

In neither case can I allow that expediency should be set up as the cause for the commission of error. This expediency is, in fact, a legislative blunder created by an Act of Parliament, which was intended to raise the standard of medical education. Had the Act of 1815 been framed on principles similar to that of the University of London, the practice would long since have ceased to exist. By the Act of 1815 the old-fashioned apothecary, with his blue bottles in his window, was raised from the position of one who sold drugs, and was paid for them as such, into the position of one who studied medical science, and was paid for his science through the medium of his drugs. Since that day the Apothecaries' Company has done much in raising the standard of medical education, in spite of the Act of Parliament; but I have yet to learn that the science of medicine has been much indebted to the Apothecaries' Company. They are examiners in physiology and anatomy, in chemistry, in medicine, in botany. As a body, they have not advanced the progress of these branches of medical science a single step. Of course, as intelligent and, for the most part, well-educated men, they have kept pace with the times, and have raised the standard of their examinations in the same ratio as the necessity for doing so has been created. But we must not be told that these are the only requisite qualifications for those to whom the regulation of medical education and examination should be entrusted.

The great blunder committed by most men in medical polity is the tacit admission and practical belief that medicine is two things; that there is one science for the higher and another for the lower grade of medical practice—one for the guinea, another for the half-crown fee;—one amount of knowledge requisite for the peer, another for the peasant;—one scale of learning for the rich, another for the poor. But what absurdity; what perfect nonsense is this. Disease is the same, *cæteris paribus*, and human life of equal value in all places and in all ranks. True, the amount of intellect and knowledge brought to bear in the treatment of disease differs with the capacity or the industry of the medical man. Why not, then, let the distinction of rank, or grade, or degree, be based on this difference? and not upon the assumption created by Act of Parliament, that one science of medicine is taught here and another there.

The great cause of this anomaly is, in my opinion, the connection of the science of medicine with a trading body as its head, and the union of the treatment of disease with the dispensing system, as a means of payment. By the establishment of a College of General Practitioners we shall retrograde to the year 1815, instead of taking advantage of the "progress" as it is developed in 1851. Every reflecting mind must in his heart, though obliged to do as others do, and as the law directs him, be disgusted with the pill, powder, and draught-system of practising medicine. If he does not *the public does*. It is a system which, as long as it is practised, will not only degrade the science of medicine, but will always keep the medical man in an inferior position in the eyes of the public, It tends, too, more than anything else, to retard the progress of medical science. So long as the contest is that of securing a good connection, and filling their books with a long diurnal list of medicine, study too often goes to sleep—men fail to keep pace with intellectual advancement—prejudice steps in—they refuse to alter or amend their mode of treatment—a certain curriculum of draughts, pills, and powders "always did good"—and so on to the end.

But let a medical man be paid for his opinion or his advice, or his medical or surgical assistance *only*, and depend upon it he will find the pressure from behind too sharp to permit his going to sleep. But we must begin at the right end—that of a system of education and examination similar to that of the University of London, and not merge all that we have been struggling to attain in an institution which will neither confer honour on the profession, add dignity to the science, or respectability to the practice of medicine; but which will be equally despised by the public and by all practitioners of medicine, who look upon their position as students in the highest, the noblest, the most enlightening of all sciences; that combination of so many brilliant and exalting pursuits into the one grand object of medical practice—the study of man in health and disease, the cure of otherwise mortal affliction, or the alleviation of human suffering.

One of my objections then, (as stated in my protest inserted in the *Journal* of January 22) to a College of General Practitioners, may be gathered from the above remarks. The very name is one which ought to be abolished in a learned profession. You might as well designate it a College of General Dealers as General Practitioners: the one would obtain quite as much public respect as the other. Why is it, I ask, that medical men are held in such low estimation by the public? Who with the feelings, the tastes, and the pursuits of a gentleman, would not blush to find himself placed before the public in company with the picture drawn by Dickens or Thackery, in their acknowledged masterly pictures of human nature. Both questions, I answer, will find a solution in the fact of his being looked upon as a dreaded person, who will drench you with physic and send you in a long bill at Christmas, in company with—

"Butchers, bakers, and candlestick makers."

And yet this reproach it is proposed to perpetuate by a chartered College. In the middle of the nineteenth century—in the days of rail-road and electric telegraphs, and of general education;—when discoveries of surpassing importance in science are daily startling the world;—when thinkers are becoming the rule of society and drones the exception, it is coolly proposed to establish a Royal Scientific College, which will give a name and a habitation, and a *prestige*, to a system false in principle, injurious to the public, and degrading to the medical profession.

But I may be anwered—there is no binding clause in the proposed Charter to enforce the system of which you complain; men may practise and charge as they like. Very true: so they can and do, now. But your new college, instead of taking high grounds and illegalising the charge for medicine, merely perpetuates the present system, with the addition of enabling apothecaries to practise and charge for surgery, which they may have never been taught, and permitting

surgeons to practise medicine which they may never have studied; midwifery and the sale of drugs being thrown in to be divided by the two.

Shame, I say, upon an enlightened age, that will for a moment entertain a position so derogatory to the true dignity and honour of medical science. Was it for this that Harvey discovered and Hunter laboured? Is there no feeling or spirit of a Cullen, a Heberden, a Mead, or a Baillie, still existing? What will such men as Brodie, or Watson, or Latham, or Louis, or Andral, or any of those rising spirits of the age—the Budds, the Garrods, the Birds, the Walshes, or the Joneses say to the prostitution of the science which they advance and honour?

But say, objectors, your system is not practicable. How can we locate chemists and druggists in remote districts? I answer. "Do not interfere with any medical man who wishes to dispense his own medicine, only prevent him from charging for it. Let every future medical practitioner have a high minimum of education to pass. When he has done so, let him take an oath to preserve the honour and dignity of his college, by charging only fees for his advice and attendance."

But say others,—Will not the medical man suffer in his interest? I answer. "No; I think he would be a a gainer in income, and I am quite sure he would be a gainer in respectability. It would not put an end to honourable competition, but at all events it would prevent the dishonourable sneaking mode of getting into practice, too often seen in the present day, that of selling mixture, pills, powders, &c., at a lower rate than men of perhaps much higher attainments." If I am asked how I would prevent competition by lower fees, I answer, "that, by my system—a higher grade of education, and a higher standing in society—could ensure more uniformly gentlemanly conduct than medical practice now can boast of."

But say other objectors—*Will the public benefit by the change?* I answer. "Immensely. If much medicine is requisite in the case, the medical man will be freed from the reproach of drenching; if not, you may depend upon it the patient will find no fault. In either case he will pay simply for what he gets, and if he is not satisfied, all I can say is, he *ought to be.*"

I have thus dilated at some length upon one of my six heads of objections to the proposed new College. I hope those who agree with me will continue to send me their names to add to a general protest, and do so as soon as possible.

I am, Sir, your obedient Servant,

C. R. BREE.

Stricklands, Stowmarket, Feb. 8, 1851.

MEDICAL POLITICS.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—I quite agree with the very excellent remarks of our associate Mr. Cartwright, contained in a recent number of the *Journal*, on the subject of your abandonment (as Editor) of all discussion respecting Medical Reform. Rely on it, your yielding to the small pressure of some gentlemen, whose opinions are of the ultra cast, will damage the usefulness of our *Journal*, and indeed deprive it of an essential part of its vitality.

Truth needs not silence, but *a voice* frank, clear, and intelligent. You give our opponents in this matter a hearing, and surely a *very small minority* ought not to govern seven or eight-tenths of the whole.

Do, Mr. Editor, write honestly, and you will succeed, nay, perhaps, even convert the unconverted; and by such a course be finally the means of uniting our body in one harmonious whole—"a consummation devoutly to be wished."

I believe the greater proportion of medical men in this locality, go for reformation in existing institutions, rather than for the establishment of new ones. When we consider the jealousies, the heart-burnings, the rival interests, the nepotism, which new institutions excite, I must say, and I speak the sentiments of a large majority of my brethren, give me a reformed College of Surgeons, rather than any new College which the ingenuity of the most clever amongst us could devise.

"Better to bear the ills we have, than fly to others which we know not of."

Once more, therefore, Mr. Editor, let me urge you to speak *what you know to be the truth*, and the almost unanimous voice of our giant association will approve, and be satisfied.

I remain, Sir, yours obliged,

EDWARD HUMPAGE.

Redlands, Bristol,
February 7, 1851.

Medical Intelligence.

THE INCOME-TAX AND ITS OPPRESSIVE EFFECTS ON GENERAL PRACTITIONERS.

[We take the following from the *Times* newspaper.]

"The usual argument in favour of the present method of assessment is stated in a few words. Income is only taxed whilst it lasts: the assessment, therefore, is fair. Let us now suppose the case of *a general practitioner in medicine*—of a man who, by the most unceasing labour, by the utmost anxiety and carefulness, is earning his £500 or £600 per annum in a country neighbourhood. We will give him every professional advantage—he shall be medical adviser in ordinary to the union in which he resides, he shall have contracted with the Grammar School and the young ladies' boarding establishment in the adjacent town to keep the systems of the pupils cool and comfortable for an annual sum certain. He shall be well with the squire; a sound Churchman, and on dining terms with the rector; and yet no violent party man, lest the Dissenting pneumonia of the country side should fly for relief to the opposition brass-plate in the county town. He can calculate the exact money-value of the zymotic, and strike an annual average upon the sporadic diseases within his beat. Altogether he is in as comfortable and permanent a position as any member of his class can occupy. There is nothing wanting to complete his felicity. He occupies a square white house neatly slated, with a little pill-box of brick and mortar attached, in which he himself or his assistant—who has paid him a premium—spreads the 'bergamy' pitch-plasters, and 'exhibits' the aloes and jalap. Behind the house is the stable with two stalls, whose inmates are never

destined to enjoy each other's society, as Mr. CAMOMILE drives one about all day and rides the other round the country all night. Now at the end of the year, with all his riding and all his pill-rolling, the unfortunate practitioner just manages to make both ends meet; for the time has come when little JOHNNY must go to school to be initiated in the niceties of Roman versification, with a view to making his way in the world at a subsequent period. The eldest daughter, ANNA MARIA, too, must be gently led in the direction of CRAMER'S exercises, and be instructed in the art of hemming pocket-handkerchiefs. Poor CAMOMILE, who was born with a kindly, genial soul, cannot but entertain the local dining club once a year at Opodeldoc Lodge, when the planned furniture of the dining and drawing rooms is divested of its brown-holland epidermis, and even the tissue paper which had been pinned round the broad gilt frame of Mrs. CAMOMILE'S portrait, for fear of fly-blows, is removed for that night only. The expense of that entertainment, which exactly equals CAMOMILE'S overpayment to the Income-tax, is probably the only expense throughout the year which will not bear the strictest investigation, but it helps, with his necessary outlays, to pull him down. The life, no doubt, is a hard one—a harder one than great politicians would readily imagine; but still, while health lasts, it is tolerable, and not without its compensation, to a man of honest and humane temperament. But the night comes, when poor CAMOMILE, who has been roused from his sleep to assist at a premature birth, at some seven or eight miles distance from his own house, rides there through the pelting rain, and sits during the anxious night by the bed-side of his suffering patient in his wet clothes. A cough follows; he cuts off his dinner, but continues his rides; his symptoms become aggravated by exposure to the weather, and in a fortnight he is beyond the reach of his own skill, and in a fortnight and a day beyond saving by any physician upon earth. He goes where we all must go; but Mrs. CAMOMILE, and JOHNNY, and ANNA MARIA, awake from their dream of security to find that their means of support have gone as well. They must content themselves with being—as political economists would phrase it—absorbed into the population. That is to say, when the two horses and the planned and other furniture, and the house, and the galley-pots are sold up, there is just enough to clear scores all round, and pay for the only spot of earth in which CAMOMILE had known the peaceful rest of an hour since the day he first established himself at Opodeldoc Lodge. Why did he not insure his life for a few hundred pounds? will be the comment of many a strong-minded person upon this faint outline of a life. Simply because it pleased the Finance Minister of his country for the time being playfully to suppose that his income would inure to his children after him, and to mulct him accordingly. To be sure he might have dropped his annual entertainment to the members of the Hawthorn Dining Club—but then some of us come from one side the Tweed, some from the other."

EPIDEMIOLOGICAL SOCIETY.

The third ordinary meeting of this Society was held on Monday, February 3rd, in the rooms of the Royal Medical and Chirurgical Society. Dr. Babington, the president in the chair. Seven members, nine corresponding, and one honorary member were admitted, and seven new candidates for membership were proposed.

A paper by Dr. Hoskins, "On the Origin and Progress of Cholera and Small Pox in Guernsey," was read by Dr. Gull. The facts recorded by Dr. Hoskins were highly interesting, for the most part adverse to the doctrine of contagion.

Mr. Grainger said that if a widely extended view were taken of the history of cholera, he thought that the diffusion of the disease appeared to be effected rather by places than by persons, and that the proof of its communicability from one person to another would be found insufficient.

Mr. Hunt admitted that at certain times, and in certain places, the disease did not appear to be contagious, but he believed that on other occasions it was clearly to be traced from person to person. He, therefore, was inclined to think that, like erysipelas, puerperal fever, and other diseases, it varied in its type, being sometimes contagious at other times not so.

Dr. James Bird said that he had seen much of the disease in India; that, in a certain sense, it was never contagious, and never thought to be contagious in that country; but that where the diseased were congregated together a degree of infection was generated; and that when it broke out among troops, many sleeping in the same apartments, its spread was soon arrested by the men being ordered into separate tents.

Dr. Gull said, that if the disease were generated by the diffusion of putrid gases, he did not see how it could ever become contagious. On the other hand, if the germs of the disease were transmitted in a solid form from person to person, a condition in some sense necessary to contagion, it was difficult to conceive that atmospheric influence alone should promote the disease.

The paper announced to be read at the next meeting in March, is "On the Yellow Fever which has lately appeared in the Brazils."

The President announced that the Treasurer had received a cheque for five guineas from David Fullarton, Esq., of Kidbrooke Park, Forest Row, Kent, as a contribution toward the funds of the Society; and expressed a hope that so good an example would be followed by many others.

APPOINTMENTS.

Mr. W. W. James has been elected one of the Surgeons to the Exeter Dispensary, in the room of Mr. W. P. Kingdon, resigned; and Mr. W. P. Kingdon has been elected Consulting-Surgeon to the same Institution.

ROYAL COLLEGE OF SURGEONS.

The following gentlemen were admitted members on Friday, the 7th inst.:—William Paul Bullock. Bristol; Edward Connor Cornelius, Upper Canada; Charles Manteiro D'Almeida Lempriere, Australia; Duncan MacCallum, Montreal, Canada; Frederick Francis Ormond, Plymouth; Philip Henry Tribe, Bengal; Watkin Sandon Whyloch, Chatham.

SOCIETY OF APOTHECARIES

The following gentlemen ware admitted members on Thursday, Feb. 6th:—Francis Thomas Van Hemert, Frodingham, Lincolnshire; William Lay Williams, Manchester.

OBITUARY.

On the 8th inst., at Hastings, James Mackness, M.D.

ERRATUM.—In Mr. Bree's "Protest," January 22, page 55, col. 1, second paragraph, for "unfair" read "inferior" College.

TO CORRESPONDENTS.

Communications have been received from Dr. Nelson, Mr. Hatton, Dr. Tilt, and Dr. Durrant.

A Frequent Reader must authenticate his communication prior to its insertion.

CLINICAL LECTURES

ON THE

PRACTICE OF PHYSIC,

DELIVERED IN THE

THEATRE OF QUEEN'S COLLEGE, BIRMINGHAM, 1849-50.

By DAVID NELSON, M.D.,

Physician to the Queen's Hospital, and Professor of Clinical Medicine, &c

[Reported by MR. WILLIAM ROGER BANKS, Student of the College and Clinical Clerk.]

LECTURE II.

On the Morbid conditions of the Brain and Nervous System, and of the Organs of Sense.

There is no part of the body where slight incipient symptoms ought to excite so great a degree of regard and anxious attention as the head. It has been my constant endeavour to impress this lesson strongly and irremoveably upon the student's mind, for trite and hackneyed as it may appear to some, it is always apt to be forgotten in actual practice, because of its very triteness, and of the puzzling and often intangible evidences which present themselves in head affections. Their appearance may take place so long after the exciting cause, such as a blow or fall, that the reason is not brought at once to see the connection between this distant excitant and the present slight symptoms. There may be merely some faint degree of mental confusion, with partial loss of memory, and consequent repetition of the same facts, or a little nausea or sickness, coupled with headache. There may be sudden screamings and excitement, and yet these may be accompanied with a very calm pulse, cool skin, and clear eye. On the contrary, there may be an unusual quietness and inclination to drowsiness, which shall be viewed as natural sleep. Or there may be a curious mixture of intense irritability on the one hand, and dozing stupor on the other, that shall give rise to the most contradictory manifestations of alternate or combined suffering and indifference, so anomalous as almost to excite the suspicion that the patient is clumsily attempting to simulate a state of disease which could not possibly exist in nature. All this has a tendency to hide from view the destructive work that is going on within, and it is often not until the young practitioner has actually witnessed two or three unexpectedly, yet inevitably fatal cases, that his mind becomes duly alive to the importance of those seemingly trivial symptoms by which the attack was ushered in.

In reviewing the affections of the brain I shall also include some notice of the affections of the spinal marrow and special senses, in fact I shall embrace not only the nervous centres, but their various peripheral expansions, as they are all connected one with another in a manner too intimate for separation in a practical point of view. The organic or ganglionic system is perhaps more decidedly distinct from the other two systems than these latter are from one another, yet it is not so entirely independent in the human body as to permit of its being placed under a separate head, while we are treating of those complicated ailments which may frequently involve all three at once. It has already been laid down as a fundamental rule in the introductory lecture, that in no case should you omit a general examination of the leading organs of the body, whether they be especially affected or not, because, in the first place, you cannot ascertain the latter fact without due inquiry; and in the second, because the condition of each principal organ must react on the rest, and may be such under the influence of this or that agent as to make you hesitate in the administration of some remedy which otherwise might be highly advisable. To omit an examination of the head under any circumstances would be palpably inexcusable. I shall dwell more fully on its condition when I treat of it as a seat of special action, but at present I shall merely point to the chief features which should engage your attention in that casual review of its condition, which should take place in every case whatever. In the first place we have to inquire regarding the existence of pain, and of what character the pain may be, for there is nothing that is more varied, or that indicates so many different conditions. It may be simply of a spasmodic kind, occurring at intervals of a greater or less duration; due to anæmia, or other causes of debility; to irregular transmissions of nervous force, or to that functional perversion of the sensific centres which are denominated hypochondria and hysteria. This pain is to be distinguished by its not being increased, but rather lessened, under exertion of mind or body, by the eccentricity of its visits, and by its being relieved by antispasmodics, stimulants, or tonics.

An organic pain will be fixed, and always aggravated under exertion, or any other stimulant to the circulation, and may depend either on acute hyperæmia or passive congestion, or any of their results, from a solid clot to a simple effusion of serum. In the event of acute action, the pain will be of a darting character, with much heat of the scalp, fiery sensitive eyes, and great watchfulness, and will require abstraction of blood, mercurial purgation, and the application of cold. In passive congestion, or in effusion, the pain will be dull and heavy, with perhaps some heat of the scalp, but the eyes will be darkly suffused, the general frame less sensitive of external agents, and the sufferer will rather be inclined to drowsiness. The pain may further be of a rheumatic nature, depending on some especial determination of irritating urinary salts which may be retained in the circulation; this is to be inferred from the general history of the patient's constitution, from the presence of contemporaneous pains in the joints, and from the state of the urine. If confined to the external parts, as it commonly is, it will readily be removed by the ordinary remedies for rheumatism, but if it involve the brain itself, or its membranes, it is likely to prove as fatal and irresistible as other affections of that organ are known to be. The headache that proceeds from derangement of the stomach or bowels, is commonly called a sympathetic one, arising from the immediate

nervous connexions that exist between the abdominal viscera, and especially the stomach and brain. At its first onset it will certainly be subdued in exact correspondence with the success which attends your treatment of the digestives, whether such treatment be directed to the neutralization of acid, or oils, or the simple expulsion of any other irritating matter, or to the removal of hyperæmia. But it will certainly sometimes continue long after the stomach and bowels have been brought back to a tolerably healthy state of action, especially when the previous complaint happens to have been of very long standing. This is especially illustrated in the hydrocephalus which supervenes as a secondary effect on the abdominal affections of young children, though it may perhaps be doubted whether the functions of any organ can ever be perfectly renewed after any protracted attack of inflammation, however mild. Another sort of headache is consequent upon very long fasting, or watchfulness, or mental effort, or any other cause of nervous exhaustion, and this of course can only be removed by nutrients and rest, aided by some stimulant, as very well instanced in the headache which succeeds a debauch, or excessive grief. I have already spoken of the heat of the scalp, of the appearances of the eye, and of the nature of the pain, as illustrative of the different forms of hyperæmia which may be supected, but may also add that the condition of the tongue has a close connection with such a state of things. Along with the bilious sympathetic headache, and that of congestion, we have a tongue thickly furred with white or brownish yellow; emetics are advisable for the first, but not for the second, if much straining be anticipated. In the nervous headache, and that which is concomitant with affections of the lesser bowels and colon, it is almost always clean, but entirely red; but as alteration of structure advances, the fur again returns, at first of a simple white, next a yellow, afterwards brown, and lastly a deep dry black. In the headache that accompanies certain enlargements and other affections of the liver, the tongue will be found of a bright pink colour, moist, and of a glassy smoothness, either in whole or in part; or, on the other hand, it will be deeply fissured transversely.

With the exception of an occasional eruption of blood from the nose we have no external discharges by which we can judge of the internal condition of the brain; yet the state of the eye gives us some evidence of the degree in which pressure may be exerting its influence. A slight turgescence of the vessels, or a slight liquid effusion, may show such marks of its presence; but a higher amount of those morbid occurrences will produce excessive contraction or immense dilatation of the pupils, along with drowsiness and diminished sensibility. It has been made a subject of argument amongst certain physicians and surgeons as to whether the contraction or dilatation indicated the higher degree of pressure, some of whom said they always observed contraction to occur in the worst cases; but where all are so bad it is difficult to decide which is worst. For my own part, I should consider that to be the worst state of affairs which is nearest death; and I have always observed, that though both pupils might have been previously contracted, or one contracted and the other dilated, yet both of them would become greatly dilated before the supervention of the fatal event. Even in ordinary cases of dilatation of the pupil, when the patients are walking about and engaged in their usual occupations, great attention should be paid to this index of cerebral pressure, generally proving an effusion into the ventricles, with disturbance of the optic lobes. It will be very commonly found associated with affections of the smaller intestines or curvature of the colon; and unless there be any likelihood that it arises from an idiosyncrasy or family inheritance we should never desist from perseverance in mercurial alteratives and local blistering until it be fairly subdued. These blisterings should be behind the ears and also over the abdomen, especially in one or both ilio-pubic regions, should any tenderness be there discovered under pressure, indicating inflammation or ulceration at the ilio-cœcal valve, or sigmoid flexure. So persistent, however, is this mild form of cerebral dropsy, and in so many persons of this aspect have I seen proofs of it after death, that I am persuaded it may exist in people almost during a lifetime, producing constant uneasiness but no fatal results, until the fluids be in such excess as to interfere with the ordinary function of the brain, and at length induce death by syncope. In all these pains and other affections of the head, except those that are merely nervous or rheumatic, it will be necessary to recollect that though sedatives may be safely employed yet narcotics ought to be strictly avoided. No harm can be done by conium, digitalis, or hydrocyanic acid, but much injury might be inflicted by the use of stramonium, and more especially opium. Hyoscyamus and hops are the two agencies of the latter class least objectionable in their effects; and both of them ought rather to be ranked with the former as sedatives. But above all let opium be eschewed, except under acute delirium, and even then let it be cautiously allied with antimony and mercury, and saline laxatives, for it will always have the tendency to increase venous hyperæmia, and promote that kind of sopor, the gradual increase of which ends in coma and death. This applies in an especial manner to children under eighteen months or two years of age, the peculiar liability of whose brains to be overcome by the deadly influence of even minute doses of this drug is now well established, and ought positively to prohibit its use in these cases, except under circumstances the most pressing and necessitous. The arrest of the functions of the brain and spinal prolongation involves instant death, so far as the animal life is concerned. This may take place from what is called shock, by which the action of the heart may be stopped in an instant, and the person die by syncope or a withdrawal of the blood circulating in the brain. It is this that occurs in those suddenly fatal cases where, without any attempt at reaction, the whole constitutional powers sink at once, either under a severe blow or an extensive scald, or some overwhelming mental sensation. It is a well estab-

lished fact, not only illustrated by various experiments, as gradual removal of the brain in animals, but also by the continuance of the heart's action under various diseases which slowly destroy the brain and chord, that this instantaneous fatality from sinking of the cardiac energies is rather due to the suddenness of the change than to the amount of injury. This kind of death is comparatively rare; and in most cases that prove fatal from the head the issue is rather traceable to the secondary conditions of inflammation or congestion. In blows and other physical shocks, called concussion, fainting is the first consequence, and the victim is found pale, pulseless, and cold; but should he not die while in that state, reaction with or without effusion will supervene, and then you will have the flushed countenance, the full bounding pulse, the stupor, the contracted or dilated pupils, the stertorous breathing, the coma, and death of apoplexy.

When death occurs from syncope except under such shocks as above mentioned, it is generally due to the anæmic condition of those who have either recently lost much blood by hæmorrhage, or by the slower drain of a protracted exhausting disease, in the latter stages of phthisis (such as the case of Sheridan, mentioned in reports) the patient will sometimes go off in syncope merely in consequence of the erect posture mechanically drawing the blood from the head. Such persons will feel comparatively easy while lying down, but as soon as they rise they have headache or giddiness, with loss of vision and threatened syncope. A milder and more frequent form of syncope occurs in weakly men and women, as an habitual matter under slight irritation. These are only partial faintings and of little moment. In all such cases, however, whether trifling or serious, the obvious treatment is to restore the balance of the circulation; first, mechanically, by placing the head as low as possible, and secondly, by the administration of stimulants, the most readily applicable one being ammonia, which, from its gaseous nature, can easily be made to reach the expansions of the pneumogastric nerve, which has most influence over the suspended functions. The attention, therefore, will be chiefly turned to the different forms of hyperæmia and their consequences as they take place within the brain and chord. But while reviewing such affections, I shall not deal with their symptoms, &c., in all that detail which belongs to a systematic course, but rather with those leading points of interest which chiefly occupy the minds of those engaged in actual practice, who wish to test the efficacy of different medicines, to settle disputed doctrines, and to confirm or refute the ordinary rule of diagnosis, by a reference to the revelation of the dead-house. And here I must remark, that without an appeal to that last court of medical truth, the brayings of folly will too often succeed in destroying the still small voice of reason, and we should never cease to advocate the cause of cadaveric examination as an essential point of duty, both with the profession and the public; I must plainly assert, that he who is content to watch the progress of the disease in the living body, and treat it again and again in the same way, without seeking to test the truth of his opinions by a comparison with the state of things after death, is utterly unqualified for his profession. He is not only groping in the dark, but he is groping for something which he does not know even when he happens to stumble on it. I have already reflected on those who look to morbid anatomy *alone* as a guide to practice, but the merely empirical recorder of symptoms, and administrator of the fashionable drugs of the day, is something infinitely worse, and we need not feel surprised if such an one should encourage the ignorant prejudices against *post-mortem* examinations, under a fearful misgiving that they might expose his own errors to the light of day. Gentlemen, let me specially admonish you, as my pupils, against this slovenly want of interest in the real results of your cases, as a deep shade of doubt must necessarily be thrown over all the opinions of that man, who is notoriously known never to seek for their verification in the one right place, but is rather content to keep them oscillating between this or that favourite authority, whose book, like himself, may be a mere compilation of unsifted gleanings, and whose days may have been spent in as little practical inquiry as his own. But to return to our special subject. Inflammation may occur in the brain and its appendages as in other organs, and may, as in the other organs, be of two kinds, either acute or chronic. The causes of an inflammation in this quarter may be of various characters: such as exposure to cold or over-excitement of the mind, or an external mechanical injury, a poison circulating in the blood. Minute distinctions have been made between an inflammation in the substance of the brain itself, and in those various membranes which invest it all round, or penetrate into its fissures or cavities. But although such divisions are very interesting and highly proper in a purely pathological point of view, there is the less necessity for entering minutely into them in this clinical course, considering that though the symptoms may be a little varied by the seat of the disease, the treatment of either case must be altogether the same. The substance of the brain itself being an insensible structure, inflammation of that tissue will generally give rise to less acute suffering than a similar affection in the membranes. It will also spread more rapidly over the latter than through the former.

In either event there will either be a very acute pain, coming with piercing shock from time to time, and causing the patient to utter wild screams, while he clasps his hands over his head; or there will be a dull overpowering headache accompanied with a sickness beyond expression, different from that which occurs under other circumstances—a "sickness unto death," as I have heard one such patient say. This state of things may be accompanied with a high fever, sensitive eyes, and a hot head, but it may also be without those symptoms, or else having taken place, they may subside very suddenly, and leave the patient as I have already observed, with symptoms of a very anomalous and contradictory kind, some that must of necessity excite alarm in the mind of the experienced, others calculated to lull the

anxiety of those who have not seen so much of cerebral disease. Hence you will witness the cool skin, the comparatively mild pulse, and the clean tongue, combined with pain, and sometimes seeming indifference, giving way from time to time to the most impatient irritability, under the slightest interference of those around.

Thus the girl, Baylis, in typhus, screamed whenever the finger was drawn across the skin; and the boy, Stewart, under his cerebral affection, though almost comatose, ground his teeth, rolled his head, and growled, whenever his eyelids where opened. All this must tend to impress upon your mind the vast importance of real clinical study. For you to enter the sick wards under no other guidance than that of those schoolboy epitomes which profess to curtail your labours by inflating you with *verbiage* instead of knowledge, and wherein the symptoms of this or that disease are laid down in the most prim and exact order, you would find yourselves staggering with confusion at every step. There is no safety but in great general principles, combined with zealous personal observation. To reach the first you must drink deeply of the profound authors of every age, not so much for technical knowledge as for correct habits of thinking; and to attain the second, you must accustom yourselves to watch assiduously the minute and varied changes which are found to occur in the progress of disease and curation. For it is no opprobrium to physicians, as some of the ignorant fondly suppose, that their art is not so certain as that of a mechanic. It is evident, from the very nature of the frame under our study, that that art can never be of an uniform and unvaried application, because there exist within each subject certain independent emotions and feelings utterly beyond our control, which shall come and go often without any apparent cause, and exert such a perturbing influence over all the functions of the body as shall greatly modify their operations under any imaginable circumstances, and so place an insurmountable obstacle against all attempts at strict uniformity of practice. All inflammation must have been preceded by some irritating cause, and here, as already observed, you will either find a revulsion of excretions determined to the head, as in exposure to intense heat and cold, giving rise to that form of disease consequent on *coup de soleil*, or that other delirium and raving madness, followed by coma, which occurred in the French expedition to Moscow, and in the black hole at Calcutta; or that which follows the absorption of alcohol and other poisons, or the poisonous retentions of rheumatism and fever. A blow, especially amongst the aged, whose arteries are brittle, may give rise to a very slight effusion of blood, which, however, will gradually increase by gentle tricklings, and at length form a clot, which may either cause death by its simple pressure, or by exciting this secondary inflammation. In every case, though the symptoms at the commencement may be obscure and uncertain, they will ultimately assume an aspect that will dispel all doubt. The bowels will usually be found much constipated and the stomach sick. Heat of the head will appear sooner or later. There will be first some confusion of ideas, afterwards irritability or indifference, or both, according to their natural temper, and then delirium and altered pupils, at first perhaps accompanied with three or four tossings of the arms and picking at the bed-clothes, but ultimately ending in partial or unusual paralysis, followed by coma and death. The delirium proceeding from acute idiopathic inflammation of the brain, however, is different from that which generally attends typhus. In the latter disease it is almost always a merely unintelligible low muttering, and it is only when the patient is of a very excitable disposition, or of the more intelligent order of society, that delirium ferox is witnessed. In inflammation of the brain, this delirium is frequently of a startling kind, considering the other symptoms of the patient. Thus, while the individual is unable to recognize any one, or understand the simplest question, being apparently deprived of all means of communication with the external world, and while the arms which had been incessantly swinging about, have become, the one of them stilted by hemiplegia, and the other reduced to slight pickings at the bed-clothes, there will be such an inimitably rapid volubility of speech—such an astonishing shifting from idea to idea, and such a reproduction of all the scenes and persons connected with them in past life, that the observer will feel astonished at the psychological phenomenon thus presented to him. It is also singular how, not only the actual instincts, but acquired habits, will continue to influence persons in this condition. I have seen a lady under such circumstances, who, feeling inclined to vomit, held her hand to her mouth while she beckoned for a bason. After this has ceased, and deep coma supervened, the organic life, if previously vigorous, may be maintained for a period of several days; but if weak, it will soon be extinguished; stertorous breathing or puffing with the lips may occur, but this is by no means constant. The muscles will be completely motionless; the pulse, which had been, perhaps, slow and full, will become more small and rapid, the face will be more flushed; the breathing will become slower; the power of deglutition will cease; the pupils will be fixed and expanded, or oscillating from side to side; the tongue will be black; the face cold, and so the scene will close without any further perceptible change, except that at two or three very long intervals there will be an expiring breath, or little catching sigh.

Such is the general history of inflammation of the brain, whether it proceed from one cause or another; and the chief point to decide is, whether it be idiopathic, or is simply symptomatic of rheumatism or fever. The key to this will be an inquiry into the previous history of the case; the principal difficulty may be in distinguishing it from the head symptoms of fever. Both may be ushered in by the same accompaniments of headache, shivering, sickness, and prostration; and if there be a probability of infection, with an absence of any evidence concerning local injury, it will behove us to proceed very cautiously in our treatment, as what might benefit one disease might prove injurious in the other. The tongue, however, and the state of the pulse will

generally prove, in no long time, what is going on, and indeed, even in the early stage, though it should be typhus. I do not see that injury could be done by some slight local abstraction of blood, and the administration of mercury and antimony, if it should so happen that the tongue was moist and the pulse very full and slow. In the event of delirium tremens, however, we must be exceedingly cautious to discriminate, as then a very opposite line of treatment would be demanded, from the importance of the organ involved, therefore, we must be very decided in our procedure from the first. Even then recovery is exceedingly precarious, and much more so in the later stages, when it becomes altogether improbable. I certainly believe that inflammation may take place in sundry instances, and that exudations may be thrown out, and serum or a clot of blood continue pressing on the brain, to be ultimately softened and absorbed along with a portion of the natural texture, and yet no symptoms beyond, perhaps, some confusion or drowsiness, and dilatation of the pupils appear in the patient. In such instances all evil consequences may be removed by nature or art. Clots, so long deposited as to have been reduced to pus, have been found in the brain without giving rise to any urgent symptoms until the end. In other cases there have appeared proofs of a total absorption. But, doubtless, under such circumstances, the injury, by some means or other, has not reached that degree or extent by which alone the essential functions of the organ could be effected; but when the more advanced symptoms begin to manifest themselves, I think they generally indicate such a change in the condition of the brain as renders any idea of cure next to hopeless. However, as instances of recovery are occasionally recorded, even after the supervention of hemiplegia and coma, it is right that we should persevere with every remedy that appears in any way to have contributed to the result. The first remedy to be thought of is the abstraction of blood, either generally or locally, according to the constitutional powers of the patient. The opening of a large venous orifice, when the patient is young and plethoric, may be advisable, otherwise the repeated application of leeches behind the ear will be the more prudent course; along with this, the head should be shaved, and a constant evaporation be kept up on its surface by means of cold light cloths, continually moistened with a sponge; the system should be put under the influence of mercury and brisk purgation should be carried on throughout. It will sometimes be very difficult to move the bowels, both because they are sluggish in themselves, and because it is not easy to administer medicines after stupor has supervened. The best agent under such circumstances is the croton oil, and it is sometimes surprising what a degree of consciousness may be excited during the action of the purgative, though afterwards the sufferer may subside into his former stupor.

That stupor, however, will sometimes be intermixed with a restless and uneasy groaning, in consequence of the intense inflation of the bowels with morbid gases. In this state it is common to find injections of assa-fœtida, &c., proposed, but the most ready and effectual relief is afforded, especially if the bowels have been previously well opened, by ordering the insertion of a common clyster-pipe per anum, and then using gentle pressure over the abdomen. By these means an immense amount of inodorous gas may be discharged, and it does not readily accumulate again. When the inflammation happens to be of a specific character there will be required, as a matter of course, in addition to the above ordinary measure, or instead of them, those that are applicable to the specific disease. When rheumatic, with an inclination to fibrinous deposit, colchicum, nitre, &c., will be called for; but when simply symptomatic, as in typhus and delirium tremens, in both of which cases the blood is exceedingly liquid and all the vessels relaxed, then wine, spirits, and other stimulants will be demanded, the quantity being regulated by its effect. In cerebral congestion, recognised by the heavy headache or sleepiness, the dark suffusion of the eye, the loaded tongue, and constipated bowels, all indicative of general torpor, the same depleting line of treatment must be accompanied with tonics and stimulants. There is, under these circumstances, an universal languor of sense and of circulation which, if not checked in due time, is apt to induce dropsical effusions and other secondary effects of greater or lesser magnitude. It is necessary, therefore, to relieve the distended vessels, and re-excite them to a more contractile energy. If the obstruction be referable to any impediment existing in the right side of the heart or at the lungs, the complaint will be more obstinate and less amenable to treatment, but will be all the more deserving of attention. In ordinary cases the best commencement of the treatment will consist in the application of a few leeches behind the ear, followed by blisters, if there be any dilatation of the pupils. Headache and heaviness may be at once relieved by this step, but they will be pretty certain to recur, unless metallic tonics and aperients be persevered with for some time. The former may consist of nitrate of silver or sulphate of zinc, or any agent of that class; while the latter may consist of croton oil or scammony and colocynth, to make a decided impression at the beginning, while afterwards single-grain doses of aloes every night, with infusion of chireyta three times a day before meals, may be suffered to complete the curative process. To prevent returns of such a condition the patient must so regulate his diet and exercise as to avoid plethora on the one hand or debility on the other. Over eating, with indulgence in heavy liquors and sedentary confinement to close apartments, constitute very common causes for this condition of the brain, and ought to be avoided. The symptoms accompanying cerebral apoplexy, whether proceeding from shock and effusion of blood, or fibrin or serum, and the treatment to be adopted under the circumstances, will be gathered from the observations which have already been made under the preceding head. And it may be only further remarked that in sanguineous apoplexy, after reaction is once established, the greatest benefit appears to have been attributable to large general bleedings, by which the action of the heart has been subdued, and the current of the circulation so diminished

as to limit the amount of effusion. The head being kept high and motion strictly forbidden also contribute to the same end. Where fibrin or serum are supposed to be present, the object is to break down the solidity of the one and absorb both; hence mercury, accompanied at first with diuretics, and afterwards followed up by drastic purgatives, promises to be most efficacious. Serous apoplexy is far less likely to prove fatal than the sanguineous or fibrinous, partly because it is capable of being more easily removed, but partly, also, because it is of less sudden accession; and, therefore, as it gradually increases up to a certain point the brain becomes accommodated to the unusual pressure, so as to be able to perform its functions even under a great degree of the effusion. This was illustrated in the case of the poor woman, Whitehall, who got rid of all her dropsical effusions and got out of bed; after eating her breakfast with enjoyment she suddenly expired without a scream or struggle, and the ventricles of the brain were found so dilated with fluid as to make the brain itself appear like a mere shell.

I have also already observed that I believe many people pass nearly their whole lives with some partial deposits of this kind, leading to incipient but yet not fatal symptoms.

February 8, 1851.

CASES OF HYDATID DISEASE, WITH OBSERVATIONS.

By C. M. DURRANT, M.D.,

PHYSICIAN TO THE EAST SUFFOLK AND IPSWICH HOSPITAL.

Case I.

Hydatid Cyst in the Right Hypochondrium: Puncture of Cyst: Recovery.

Thomas Skipper, aged 35, a shoemaker, admitted as an out-patient of the Ipswich Hospital, July 24th, 1849, of whose previous history the following facts were elicited:—He stated that he had not been intemperate, but that he had habitually drunk a large quantity of malt liquor. He had felt pain in the right side for between four and five years, and for the last six months he had remarked that the side had become considerably larger. He was much emaciated and looked wan and care worn, but in all other respects his general health was perfectly good. On examination, a large fluctuating tumour was found occupying the right hypochondriac region, rendering prominent, and extending below, the false ribs. Its surface was smooth and even, but not in the slightest degree painful on pressure. The fluctuation was more distinct at the first examination, but it subsequently became very obscure. His lungs and heart were healthy.

The treatment consisted of the successive application of three blisters, with full doses of the iodide of potassium. These measures proving, however, ineffectual, paracentesis of the tumour was decided upon, and performed by my colleague Mr. Bullen, August 27, 1849, when six pints of limpid colourless fluid were drawn off, its specific gravity 1012, alkaline, but not albuminous. The microscope developed merely crystals of alkaline salts. The sac having refilled, Mr. Bullen again introduced the trocar on the 10th of September, when two pints were evacuated. The fluid was now albuminous, and of an amber colour, alkaline salts appearing as before under the microscope. A flannel bandage was firmly applied to the body after each operation.

The sac partially refilled, but a third operation was unnecessary. The fluid was absorbed, the sac collapsed, and under the use of cod-liver oil, the patient became, and still continues, stout and strong.

Case II.

Hydatid Cyst in the Right Hypochondrium: Cyst Punctured: Recovery.

Mary Pegg, aged 43, a healthy looking woman, residing in the country, was admitted into the Ipswich Hospital, July 21st, 1849 She stated that she had had an enlargement of the right side for four years, that it had increased gradually, and without pain, her general health had been uninterruptedly good, and she had never been the subject of jaundice.

On examination, a convex prominent tumour was found occupying the right hypochondrium, the edge of which was felt well, and abruptly defined about four inches below the false ribs. Fluctuation was so indistinct that its existence was rendered almost doubtful

Paracentesis of the tumour having been decided upon, an exploring trocar was introduced by my colleague, Mr. Bullen, and sixteen ounces of a limpid fluid of a specific gravity 1015, and not coagulable, were drawn off. The microscope indicated the presence merely of a few alkaline salts. At the expiration of seven weeks, the sac having become refilled, it was again punctured and three pints of fluid, of a similar character, were now evacuated.

After each operation the body was firmly bandaged; the patient was directed to keep perfectly quiet and to avoid speaking, and a grain of opium was administered night and morning for three days. The sac did not again refil, and the patient's recovery was complete.

Case III.

Hydatid Tumour of Liver, Simulating Chronic Pleuritic Effusion: discharge of Hydatids through the Bronchi and Intestinal Canal: Recovery.

James Keeble, aged 35, an agricultural labourer, was admitted into the Ipswich Hospital, December 6th, 1849. His conformation was short and strongly built, and he stated that he had enjoyed good health up to the time of his present attack, which he refers to a cold and "inflammation of the chest," under which he laboured eighteen months previously, and since which period he had been subject to repeated attacks of cough and expectoration, disabling him more or less from work.

On admission, his countenance was sallow and muddy; expression, heavy and dull, but not anxious; tongue tolerably clean; appetite good; bowels regular; urine largely depositing lithates. Pulse about 100, regular, and of fair strength. Emaciation inconsiderable; cough troublesome, particularly at night; expectoration sanguineo- and muco-purulent, to which he had been subject previous to admission. Decubitus chiefly dorsal.

On examination the right chest was found to be rounded, and measuring half an inch larger than the opposite side. Intercostal spaces also slightly dilated, and tense. Vocal and tussive resonance abolished on the right side. Percussion afforded a dull sound over the entire right chest, both before and behind, but much more pronounced at the base. Respiratory murmur very feeble over the upper portion, but quite inaudible throughout the base of the right lung. Modified bronchophony and occasional muco-sibilant rattles obtained over the right scapular region. Position appeared to alter somewhat the intensity of the breath-sound, rendering it more distinct when the patient inclined upon his face. There was exaggerated respiration throughout the left lung.

The case having been regarded as one of chronic pulmonary induration, with effusion into the pleura, together with some bronchitis of the larger tubes, his treatment consisted of repeated blistering, mercury, and the free use of the iodide of potassium. These remedies, while they effected an improvement in the general health, failed in producing any marked change in the physical signs.

At this period (about five weeks after the patient's admission into the hospital,) he complained of pain below and beneath the false ribs on the right side. Upon examination, a small, rather deeply-seated, pulsating tumour was discovered, about an inch to the right of the ensiform cartilage of the sternum. The tumour was unaccompanied by murmur, and was only slightly painful on pressure. At this time the expectoration had increased in quantity, of a dirty purulent character, largely mixed with blood, but without odour. Although empyema was suspected, still the physical signs remained unchanged, and no sound indicative of a fistulous communication with the pleural cavity could be detected on the most carefully-repeated stethoscopic examinations.

The patient continued in the same position for some days longer, expectorating copiously, but *without corresponding emaciation*, and with a continued good appetite. He now, at the usual visit, produced for inspection what he termed skins, which he had that morning expectorated, and similar portions, which also he said that he had been passing for some days per anum, mixed with the evacuations. On examining these membranes, collected both from the expectoration and from the fæcal matter, they were found to be collapsed acephalocysts, containing in their interior the peculiar echinococci. The expectoration, and the occasional discharge of cysts, both through the lungs and bowels, continuing, an issue was inserted about three inches below the right mamma, and cod-liver oil, with a very generous diet of meat and porter, were prescribed. Under this treatment the patient's health steadily improved, the discharge of hydatids ceased, together with the expectoration, and when he left the hospital, (April 1st, 1850,) both the tumours had disappeared, and a generally healthy condition of lung had obtained. This patient has since worked very hard during the late harvest, regardless of weather, and on meeting him a few days ago, he assured me that he continued in perfect health. I may add, that when I last examined his chest, the only abnormal physical indication was very slight insufficiency of the vesicular murmur.

Case IV.

Hydatid Tumour of Liver, connected with the Kidney: discharge of Hydatids, Pus, and Bile with the Urine: Recovery.

Mary Stopher, aged 30, married, but has had no family, residing in the country, admitted into the Ipswich Hospital, June 13th, 1850. The history of this case was extremely obscure. She first presented herself as an out-patient, complaining of pain in the right inguinal region, with difficult and painful micturition. On examining a specimen of her urine which she had brought with her, it was found to contain both pus and hydatids in large quantities, and she was at once admitted as an in-patient of the hospital. She stated that four years ago, without any assignable cause, she first felt a "weight and uneasiness" in the right hypochondriac region, which has remained more or less permanent; and that for the last twelve months she had noticed a fulness and hardness in the same situation. She had also, at intervals during the past year, remarked that her urine contained (to use her own words) "skins mixed with corruption;" and that on these occasions she suffered very severe pain in micturition. She was a short healthy-looking woman, of a highly exciteable nervous temperament. She also stated that she had been for some time under medical care, but that her symptoms had remained unchanged. With the exception of considerable debility her general health appeared to have suffered very slightly. The countenance was ruddy; conjunctiva and complexion generally slightly tinged with bile, but she had never had jaundice. Tongue clean; appetite moderately good; bowels regular; catamenial flow healthy; urine very variable, sometimes clear and limpid, at others largely depositing lithates, or again, containing a very considerable quantity of pus and hydatids, and occasionally bile. The acephalocysts varied from the size of a large walnut to that of a pin's head; the larger hydatids containing abundant specimens of echinococci. Her pulse was 80, rather weak. Heart and lungs healthy. On examining the body, a well-defined tumour of about four inches diameter was found protruding below the false ribs on the right side. It was not painful on pressure, neither could fluctuation be rendered perceptible. An interesting circumstance has

become evident, viz., that the tumour considerably diminished in size upon each discharge of pus and hydatids with the urine, and again refilled and resumed its original size in the intervals.

The treatment by cod-liver oil and issue having been apparently so signally beneficial in the case of Keeble, this patient was at once allowed a generous diet, with porter; an issue was established over the site of the tumour, and cod-liver oil was administered internally. Under these remedies the discharge, as in the former case, gradually diminished, the pus and hydatids subsiding simultaneously, while the tumour progressively became less, and she left the hospital well on the 24th of August, 1850, having been directed to keep a discharge from the issue, and to continue for some time longer the use of the oil.

I examined her side about a month ago, when no vestige of the tumour could be detected.

Observations.—In offering a few practical comments upon the preceding cases, I may first remark upon the somewhat singular coincidence of the occurrence in the same small hospital, within twelve months, of four cases of a decidedly rather rare form of disease, and which, in all probability, may not again obtain under similar circumstances for many years.

It is not my intention to enter upon the history and pathology of hydatid disease generally, as this subject is in the current numbers of our *Journal* undergoing so full and masterly an exposition at the hands of Dr. Duncan, of Colchester. One or two points, however, in reference to the preceding cases, call for a few passing observations.

The two first detailed are examples of solitary acephalocysts, containing no floating hydatids; and they are particularly interesting in reference to the treatment adopted and its results. The only two medicines, as stated by Dr. Budd, that have been supposed to have the power of arresting the increase of hydatid tumours are the iodide of potassium and common salt. The full exhibition of the former of these, both externally and internally, was steadily tried, without effecting the slightest change in the hydatid growth. This failing, the question of puncture was mooted, and subsequently had recourse to with signal success.

Notwithstanding the apparently innocuous properties of the limpid fluid contained in acephalocysts, few foreign matters coming in contact with the peritoneal surface, produce such rapid and intense inflammation of that membrane. "It would seem," says Dr. Budd, in his admirable work upon "Diseases of the Liver," "that the bursting of an hydatid tumour into the sac of the peritoneum, causes death as surely, and just as speedily, as the bursting of an abscess, or as perforation of the stomach and bowel."

With these facts before us, the question will naturally suggest itself, how far the practitioner is justified in risking the operation when the tumour is small, and productive of no distressing symptoms. Under these circumstances, non-interference will be, perhaps, advisable. When, however, the tumour is large, and steadily increasing, and when from its size and position it causes distress to the patient, then I believe it will be proper to evacuate the fluid by trocar and canula, and with certain precautions, the operation may be considered as safe as the opening of a deep-seated abscess in a similar situation.

The points to be especially attended to in reference to the safety and well-being of the patient are, I believe,—1st, to maintain firm pressure below and around the tumour during the evacuation of its contents; 2nd, prior to removing the pressure to apply a compress and bandage firmly around the abdomen. 3rd; to insist upon the patient not only abstaining from all exertion, but even from speaking for at least twenty-four hours after the operation; and, 4th, to keep him under the decided influence of opium for forty-eight or sixty hours after the withdrawal of the fluid. With these precautions the evacuation of the contents of an hydatid cyst may, I believe, be undertaken with every prospect of a successful issue.

The third case, that of Keeble, is replete with interest, both in reference to the obscurity of the diagnosis and its happy termination in recovery. It will be seen that the patient dated his illness to cold caught eighteen months prior to his application at the hospital, and although he had been partially relieved, and even able to do some work, still at intervals cough and expectoration recurred, disabling him from following his employment as a labourer.

The symptoms and physical signs were essentially those of chronic pleuritic effusion, with condensed lung and bronchitis of the larger tubes, and until the expectoration of collapsed hydatids, such was believed to be the nature of the case.

The result of treatment hitherto, while it somewhat benefitted the general health, failed in producing any decided change in physical signs. At this period, *i. e.*, five weeks after his admission into the hospital, a small pulsating tumour was first discovered below and beneath the false ribs on the right side, and although the tumour itself was but slightly sensitive to pressure, he nevertheless now complained of constant pain and uneasiness in the right hypochondriac region. The tumour was unaccompanied by murmur, neither did its history predicate aneurism. Again there had been no distinct rigor, or other general disturbance, indicative of hepatic abscess.

The expectoration now became very profuse, bloody, and purulent; still the appetite continued good, and there was no corresponding emaciation. These symptoms we find persisting some days longer, when the evacuation of hydatids, both by the lungs and bowels, at once cleared up the nature of a previously very obscure case. The acephalocyst, in this instance, had probably compressed, and at the same time produced extensive and increasing irritation of the lung. This position, I think, we are justified in maintaining, from the circumstance of the comparatively speedy return of the organ to a healthy condition after the evacuation of the contents of the hydatid cyst. The inner surface of the sac of the parent hydatid had probably taken on

suppurative action, and subsequently made its way both into the bronchi and intestinal canal, while adhesive inflammation, forming union with the adjoining viscera, had been going on in the tissues surrounding the sac.

The above case beautifully illustrates the wonderfully adaptive power of nature in promoting a safe return to healthy function.

The history of the 4th case (Mary Stopher) was extremely obscure, and presented many points of great interest. The disease, as is usually the case with hydatid growths, was essentially chronic in its progress, giving rise at first to but slight uneasiness, which, persisting more or less for three years, was followed by intumescence of the right hypochondriac region. There we find suppurative inflammation, as in the former case, set up in the outer sac of the acephalocyst, which also becomes glued to the kidney by adhesive inflammation of the intervening tissue, and thus a communication is established through which channel the contents of the cyst, viz., pus, hydatids, and bile, find an outlet. The site of the hydatid tumour, and its communication with the kidney were established by the circumstance of the escape of bile with the urine, and the interesting phenomenon presented by the alternate decrease and increase of the size of the tumour, varying as it did with the amount of pus and hydatids discharged.

Had not the presence of bile in the urine indicated the hepatic origin of the tumour, it would have been more reasonable to have referred its probable site either to the kidney itself, or to its supra-renal capsule. It may also be interesting to observe that some of the hydatids discharged were entire, and contained a perfectly limpid fluid, notwithstanding the urine in which they floated was thickly purulent.

In reference to the medicinal management of hydatid formations, with a view to arrest their growth, but little satisfactory information can be advanced. In the treatment of the two last cases, which have been detailed, a very unmistakeable improvement in each followed the establishment of a discharge from an issue inserted over the tumour, together with the internal exhibition of cod-liver oil.

Although we are not justified in forming deductions from two cases, still I would strongly recommend, when the evacuation of an hydatid cyst by operation is not deemed advisable, that, instead of wasting time and possibly debilitating the patient by giving mercury and iodine, we at once effect a free discharge by issue over the tumour, administer cod-liver oil internally, and support the strength at the same time with as generous a diet as the condition of the system will bear.

CASES OF CHOREA,

TREATED SUCCESSFULLY WITH CARBONATE OF IRON.

By T. BROWN, Esq., Castle Donnington.

Case I.—John Potter, aged 20, living at this place, by trade a painter, was placed under my care March 20th, 1847, a victim of chorea. The symptoms were unusually severe, and required the employment of energetic measures. Copious depletion, from both the temporal artery and the median cephalic vein, was resorted to, and on account of threatened violence, a strait jacket was at once applied. So much were the voluntary muscles agitated, that when he attempted locomotion, his body was propelled in all directions, producing the most antic motions. When questioned he can only answer by monosyllables. After the copious depletion referred to, and the administration of some strong drastic cathartics, the violent symptoms greatly abated. During the three following days the violence of the symptoms continued abated, and the convulsive motions were chiefly confined to the upper and lower extremities. At this period, March 27th, I met Dr. Heygate, of Derby, in consultation on the case, and we agreed to administer the following:—R. Hydr. Chlor., gr. v.; Conf. Rosæ Can. q. s., ut fiat pilula alternis noctibus sumenda.—R. Dec. Aloet Co., oz. iss.; Pot. Tart., dr. j. M. Fiat haust cras mane sumend. Ferri Carb., scr. ij., ter in die sumend.

I may here mention, that I had for several days previous to Dr. Heygate's visit passed electric shocks through our patient without any relief, in fact I really thought the symptoms aggravated by the treatment. From the period that iron was administered, (the dose of which was gradually increased,) there was evident improvement in every respect, and on or about the 20th of April our patient was quite well.

Case II.—Mary Mugliston, aged 9 years, was seized with chorea on or about the 10th of November, 1850, and the symptoms gradually increasing, on the 20th my assistance was required. I found my patient incapable of walking, speech was prevented, and the want of power over the voluntary muscles evidenced a true case of St. Vitus's dance. Judging from the apparent irritation of the pituitary membrane, in conjunction with anorexia, that the bowels gave lodgement to some vermes, I commenced the treatment of the case by giving half-drachm doses of Ol. Terebinth. on sugar, three times a-day, the result of which was the expulsion of a large worm, of the lumbricus species. Afterwards drachm doses of carbonate of iron, combined with small quantities of Pulv. Curcumæ, was given three times a-day, and the effects were most satisfactory, and to me very pleasing, the child's power over all the voluntary muscles gradually returned; and a singular feature in the case was, that *the tongue* never failed to indicate the progress of this most satisfactory return to perfect health, which occurred on the 29th of December, 1850.

MANSLAUGHTER FROM A BLOW ON THE HEAD WITH THE FIST, CAUSING FRACTURE OF THE INNER TABLE OF THE SKULL.

By J. DEANE, Esq., Chatteris.

On the afternoon of Saturday, the 28th of September, 1850, a labourer named John Ladds, was killed by William Germain, labourer, both of Chatteris. There was no previous malice; they had always before been on good terms as companions and fellow-workmen. A few angry words having occurred between them, Ladds

took off his jacket declaring he would beat Germain. Threatening then became mutual. Ladds ran to Germain with all the posturizing of the pugilist, preparing to strike him, when Germain struck him on the head above the ear, on the left side, and Ladds instantly fell, a corpse. I saw him in about an hour. He had the aspect which a young man would present who had died in perfect health. The only abnormal appearance was occasioned by a quantity of froth which was constantly issuing from his nose and mouth. On the Monday following I made a *post-mortem*. Instead of froth, a quantity of blood was found issuing from his nose and mouth, and on the slightest movement given to the head, blood, perfectly fluid, would escape to any amount. On the examination of the external surface of the skull at the spot described by the witness present at the time of the injury, there was some little vascularity, and an imperfect elevation of the pericranium on the left parietal bone, directly below the parietal protuberance. On removing the upper part of the skull I found a lineal fracture or crack of the inner table of the skull, without depression, to the extent of more than half an inch. Along the seat of the fracture a small vein was seen ramifying and ruptured. We had a good deal of trouble in removing the skull cap, its natural adhesions to the dura mater being in this case very strong, but at the spot of injury, there was no adhesion, and over the greater part of the left side of the head blood was freely effused and perfectly fluid. There was no other trace of injury or of disease, and all the other organs were healthy, but the blood throughout the whole system was, as is usual in cases of sudden death, fluid. The body was in a most offensive state of putrefaction, although he had been dead only thirty-eight hours.

This case is interesting for two special reasons :—The fluidity of the blood and rapidity of putrefaction of the whole system have a bearing on the average of mortality after severe injuries. This case and many others that might be recorded, furnish the best possible reply to the question—"How is it that amputation after serious accidents occurring in healthy people are so fatal." The notion, *a priori*, would seem to be, that if a man has a comminuted fracture of the leg, and if the limb is removed directly, the remainder of the body is sound, and that the wound so made is in the condition and has a reasonable chance, about equal to the probabilities of an ordinary wound of similar size, inflicted with a sharp instrument on any other merely muscular part of the body and unpreceded by a general shock or concussion, or by any process of crushing to the nervous or arterial systems. We often find the stump mortify ; we often meet with consecutive abscesses, phlebitis, &c. The case now narrated illustrates this most important surgical question. A man in perfect health receives a blow on his head, is stunned, and does not rally : he dies on the spot. In thirty-six hours he is putrid. The condition of the system instantly produced by the blow, is the leaven that engenders in a few hours, the same sort of putrefactive changes which a month's illness with typhus will sometimes effect. Suppose he had rallied from the concussion, and had, in his fall, received a compound fracture of the leg, it is not to be supposed that the vital powers could so rapidly and so completely overcome the injuries produced by the shock, as instantly to bring him back into the condition of perfect health. The man has a fractured leg, but besides this *he is ill;* every tissue is for a time diseased. This is at once the best and the most recent* explanation of the awful averages of failure in so many operations, but especially of the consecutive abscesses following severe lesions, which are always most to be expected in proportion to the severity of the primary injury.

I will conclude this subject with a quotation from Mr. James's valuable "Essay on the Causes of Mortality after Amputations." "The immediate effects of violent injury are impressed on every system of the body. The heart falters, the stomach rejects its contents, the liver ceases to secrete, or secretes perverted bile, the nervous system is beat down, and the countenance betrays the deep defailance ; clammy sweats, tremors, and other consequences of nervous depression occur ; but these all pass away. These various systems after a while recover themselves ; but still a tendency to diseased action remains which did not exist before, and this tendency to diseased action is produced by the impression made on the system at the time the injury was inflicted ; and although the immediate effects, as mentioned above, may pass away, this tendency remains." Whence does this arise ? "I believe," says the same writer, "that it does arise from the changes wrought in the blood at the time the injury is inflicted, communicated originally through the nervous system, but persisting long after the direct operation of this cause has ceased."

This case is recorded not merely as an illustration of an important surgical doctrine, it has also a medico-legal bearing. It is a case of death from the first blow in a pugilistic encounter. Our Magistracy and the law itself will often inquire, in the investigation of cases of assault, "Who struck the first blow ?" It seems to be almost a maxim that any preparations for a common assault will not justify the infliction of a blow in self-defence ; that obedience to the law requires a patient waiting till some positive infliction is given—till the first blow is struck, and that blow may be death. The initiative of these brutal contests is, we know, generally harmless ; but reason suggests, and this case decides, that it may readily be fatal, either from misadventure or from severity. The only witness present at the death of Ladds said, on oath, that the blow did not seem to be given with any amount of violence. Such cases as these must lead the administrators of the law to deliberate before they justify in all cases the ordinary maxim on this subject. We all deprecate these brutal encounters ; but self-defence seems to demand that where an angry comrade gives unequivocal proof of his intention to do bodily harm we are not to judge too hardly of the man who, with no previous malice, and merely to

* See Humphry's Lectures, No. X. and seq.

repel an assailant, is so unfortunate as to deal out to another the very sort of death which, had he been one moment later, he might have himself received, and under precisely similar circumstances. It is quite clear that had Germain waited till Ladds struck him, Germain might have been the next moment a corpse, and Ladds the policeman's prisoner, because one was just as likely to give a fatal blow as the other. The only circumstance that seemed to make the case manslaughter, was, that Germain made no effort to avoid the contest. The Coroner, in a very able summary of the particulars of the case, admitted the difficulty which I have detailed, and said that if Germain had done anything by word or deed, even by a cautionary or conciliatory expression, he should have considered it a case of accidental death; but that one party having given, and the other having immediately accepted, the challenge, each was equally responsible for results; and the Jury entertained the same opinion. The case will be investigated in a few weeks at the Cambridge Spring Assizes.

Chatteris, Cambridgeshire,
Jan. 28, 1851.

[There is another point of view in which this case is interesting to the student of medical jurisprudence. It has been generally held that no blow of the human fist can cause fracture of the skull, and this doctrine was maintained by the judge before whom a man of the name of Maiden was tried, for a similar case of manslaughter, at the Worcester assizes, some years ago. In that case a fracture was found extending from the occipital protuberance to the ala of the sphenoid bone. Evidence was produced that a violent blow had been given with the fist over the ear, which was much discoloured, as were also the neighbouring integuments, and beneath the temporal bone a large quantity of extravasated blood was found. But there had been a fall on the pavement, and the judge charged the jury that the fracture must have been occasioned by the fall and not by the blow. We are not aware that there is any case on record so clearly proving the possibility of fracture of the skull by the mere blow of the human fist, as the one now published by Mr. Dean.—Ed. J.]

Hospital Reports.

BRISTOL ROYAL INFIRMARY.

SURGICAL CASES ADMITTED UNDER AUGUSTIN PRICHARD, ESQ., SURGEON TO THE INFIRMARY.

Case II.

Rupture of the Liver.

— Dobbs, aged 28, was admitted about four P.M. on the 21st of September, 1850, having been crushed between two heavy boilers immediately before his admission. He was in a state of complete collapse, from which he could not be roused, but which gradually increased until he died, about one hour after he was placed in bed.

Post-mortem examination.—All the organs of his chest were quite healthy; his abdomen was filled with coagula and fluid blood. The only injury here (besides slight ecchymosis upon the mesentery and omentum) was rupture of the liver, which was completely broken into two parts; the right lobe occupying its usual position, but the left had been altogether separated from the rest of the organ, and had fallen far back into the left hypochondrium.

This case is worthy of record from the extent of injury to the liver, and the entire freedom of every other part of the body from any share in the effects of the accident.

Case III.

Imperforate Anus; Life prolonged to the 102nd day without Evacuation.

Emily Plumley was born on the 11th of June, 1850; and a day or two after birth it was noticed that she was unable to pass the contents of the intestinal canal as children usually do. The parents, however, took but little notice of the fact, as one of the neighbour's children had had a similar condition of parts, and had lived comfortably for more than a month.

When the child was a month old it was admitted as a patient at the Infirmary. An examination of the nates disclosed a well-formed anus, into which the point of the little finger could be passed, and through which a probe or director might be made to enter about a quarter of an inch, when it met with firm resistance. She had never passed any meconium or other contents of the intestine, but she passed water freely, took her natural food as infants ordinarily do, and had not been sick nor apparently in any way uneasy.

Upon consultation it was considered a very favourable case for an explorative puncture, to be followed up by passing a curved trocar in the suitable direction along the curve of the sacrum, for as there was a naturally-formed anus it was more than probable that the greater part of the rectum was also there. To this the mother would not consent, although the certain death of the child, if no operation was performed, was pointed out to her; and she accordingly took it away. One of the students, however, found out where she lived, and kept his eye upon the case. The child died on the 21st of September, having lived one hundred and two days, or more than three months, without ever having had an evacuation of the bowels, and having been scarcely at all sick. It never threw up anything like fæcal matter, but now and then a little of the mother's milk regurgitated, as is the case with most children. In fact, the mother stated that it was scarcely as sick as her other children were at the same age.

Post-mortem examination, Sept. 23.—The limbs were very thin. The abdomen much swollen; the circumference of the body measured twenty inches and a half, and it was twenty-one inches and a half in length. The organs in the chest were quite sound; the liver was of a dark purple colour externally, but had a more natural appearance when cut. The stomach and first part of the small intestine were in a natural state; but about

the end of the jejunum it began to be dilated, and all the lower part of the ilium was enormously distended, so as to be really longer in calibre than that of an adult; its contents were almost entirely gaseous. The cæcum was situated in the right hypochondrium, immediately below the liver. The large intestine was also much dilated, and at the lower part of the rectum measured at least four inches in diameter. At the sigmoid flexure there was a slight contraction, so that the rectum itself appeared like a large and separate pouch, and this was full of yellow aud fluid fæcal matter. The muscular structure of this part of the alimentary canal was much hypertrophied, and large and distinct bands of fibre could be seen surrounding the cul de sac of the rectum. The termination below was a rounded fibrous cord, as thick as a crow quill, leading to the anus; and there was not more than a quarter of an inch between the lower part of the pouch which has been described and the highest point to which a probe could be passed through the natural aperture below. The kidneys were healthy; the bladder was distended with urine; and the ureters were very much enlarged in their canal, from the constant pressure exerted by the rectum upon the organs within the pelvis. There was a short diverticulum projecting from about the middle of the small intestine.

This case appears to me to be of considerable importance; for it shews beyond a doubt that if a child is otherwise healthy we need be in no great hurry as to operative proceedings; and that the milk of the mother is so well adapted for the nutriment of the infant that although it lived for three months and never had any evacuation, the collection of fæcal matter was only sufficient to fill the distended pouch in the rectum, and probably amounted to half a pint. Of course, also, any operation that might be undertaken in such a case would be rendered easier by a larger collection of fluid contents in the intestine.

Case IV.

Removal of a portion of Bougie from the Urethra and section of the Stricture.

James Allen, aged 30, had been troubled with a stricture of the urethra for ten years, for which he has treated himself by passing small bougies lately, made of gutta percha, of about four inches in length. He has been in the habit of passing the instrument into the stricture, and of walking about with it in his urethra, without taking any steps to prevent it falling out or slipping in. The stricture is situated just anterior to the scrotum. On the 10th of August, 1850, the bougie slipped behind the stricture, and he has been unable to get it forward again. This accident, he says, has occasionly happened, but never with so large a bougie as the present one, and he has always been able, hitherto, to drive it out by passing water.

He was admitted on the 12th, suffering no inconvenience from the existence of the bougie in the urethra; the anterior extremity presents just before the scrotum, and the posterior end is not to be felt, even with the finger in the rectum. He makes water freely. A No. 5 sound will pass in readily through the stricture by the side of the foreign body into the bladder. The bougie slips backwards when the sound is introduced, but is driven forwards again when he makes water.

After trying with the urethra forceps and various instruments to withdraw it, but in vain, as it was itself of the full size which the stricture would allow to pass, it was determined to remove it by operation, as there was a constant fear of its slipping back altogether into the bladder.

Holding the bougie forwards against the stricture, I made an incision through the spongy portion of the urethra, until the end of the instrument was exposed and turned out; it was not withdrawn until a catheter had been passed through the wound into the bladder. A director would readily pass from the orifice of the urethra to the wound, but a No. 6 catheter was too large to enter the stricture, I therefore passed a sharp-pointed bistoury from the wound towards the natural orifice, and slit up a portion of the canal. A second cut was necessary to divide the whole of the stricture, which grated as in the section of cartilage. A full-sized silver catheter was introduced through the entire canal and retained in the bladder.

13th.—A good deal of the urine has passed through the wound; he has not slept well, and complains much of pains in the stomach and back. During the latter part of the day the urine has chiefly flowed through the catheter. To have an opiate at night.

14th.—The catheter does not trouble him much. The urine does not escape through the wound. A little blood appears to be mixed with the water.

15th.—During the night the catheter escaped from the urethra, but it was introduced again without any difficulty. Some of the urine escapes from the wound. I removed the catheter in the evening, having observed that in Mr. Symes' published cases he does not consider it necessary to leave it in so long as has already been done in this instance.

16th.—Most of the urine comes through the wound, but some through the entire canal. Urine turbid, and apparently containing pus.

After this date the urine escaped entirely through the wound for three days, when I passed a gum elastic catheter with some difficulty through the stricture, which was evidently closing again, and as he was able to manage it himself, he was directed to introduce it whenever he passed water. Under this plan he improved, and the wound gradually contracted, until but a small opening remained, through which a drop or two of urine occasionally escaped. After applying a piece of nitrate of silver daily to the surface of the fistulous opening, and introducing a small pledget of lint so as to induce a little granulation upon the surface, I passed a thin "insect" pin, (such as is used for twisted sutures,) deeply and transversely across the wound, as nearly as possible at the edge of the urethra, and placing a piece of leather on each side to protect the skin, I brought the sides firmly together with a twisted suture. The pin was removed in two days, but the skin did not appear to have healed, although the deeper part of the wound

may have closed; and he went out the next day, with directions to return if he felt any inconvenience from the stricture, or if the fistulous opening remained. At the time of his going out of the infirmary, the urethra, at the place where the stricture had been, would readily admit a full-sized catheter.

I have seen nothing of this patient since, and therefore conclude that he remains cured up to this time. He remained six weeks under my care; and I cannot but think the time would have been very much shortened if I had kept an instrument in his bladder until the external wound had healed, instead of removing it on the fourth day. If he appears again with any return of the stricture, or other symptom of importance, it shall be recorded.

Provincial Medical & Surgical Journal.

WEDNESDAY, MARCH 5, 1851.

We take notice of this case, (The Queen *v.* the Inhabitants of Minster,) which has been recently decided in the Court of Queen's Bench, and is reported in the twentieth volume of the Law Journal Reports—Magistrates Cases, page 48—because it involves a point especially worth the notice of all medical practitioners who are engaged in the care of the insane. We will first state by way of preface, what are the present directions laid down by the law as to the admission of pauper lunatics into an asylum, information which may be found useful by many of our readers.

The statute 8 and 9 Vic., cap. 126,* is now the ruling authority on this point. By the 48th section of that act the medical officer of any parish or union who is aware that any person chargeable thereto is a lunatic, is bound within three days to give notice of the fact to the overseers. Within three days after the overseers must give notice to a justice, who must within the like time order the (supposed) lunatic to be brought before him, (or if necessary, go to his or her abode) and "shall call to his assistance a physician, surgeon, or apothecary, and examine such person; and if upon view or personal examination of such person, or from other proof, such justice shall be satisfied that such person is a lunatic, and such physician, surgeon, or apothecary, not being the medical officer of such union or parish, shall sign a certificate according to the form in Schedule (E.) No. I., to this act annexed, that such person is a lunatic, idiot, or insane person, or a person of unsound mind, such justice shall, by an order under his hand direct such person to be received into the asylum of the county or borough, in which such parish is situate, &c."

By the 50th section, if any medical officer omit to give such notice, he becomes liable to a penalty of £10 for every such offence.

By the 51st section this certificate is to be "dated not more than seven clear days previous to the reception of such patient," and "every person who shall receive any pauper or other such person as is hereinbefore mentioned into any asylum without such order and medical certificate, shall be deemed guilty of a misdemeanor." The following is the form of the certificate:—

"I, —— ——, being a Fellow (*or* Licentiate) of the Royal College of Physicians in London, (*or* a graduate in Medicine of the University of ———, &c., *or* a Member of the Royal College of Surgeons in London, *or* an Apothecary duly authorised to practise by the Apothecaries' Company in London,) hereby certify that I have this day personally examined A.B., the person named in the accompanying statement and order, and that the said A.B. is a lunatic, (*or* an insane person, *or* an idiot, *or* a person of unsound or imbecile mind,) and a proper person to be confined.

(Signed)
Name.
Place of abode.

Dated this day of 18 .

Such being the general law, we proceed to notice the particular point in question. Two justices having made an order on the parish of Minster for the maintenance of a pauper lunatic, the churchwardens and overseers appealed to the Court of Quarter Sessions for Cornwall. The Court confirmed the order, subject to the opinion of the Court of Queen's Bench on the case, which was accordingly argued before that tribunal. Amongst other grounds of appeal was one that the medical certificate was not made in the form prescribed by the act. The certificate sent in was as follows:—

"I, E. L. West, *being a surgeon,* do hereby certify that I have this day personally examined J. Davey, the person named in the accompanying statement and order, and that the said J. Davey is an insane person, and a proper person to be confined.

(Signed) E. L. West.

Dated, &c.,

After hearing the argument the Court reserved judgment, which was afterwards delivered by Lord Campbell (*inter alia*) as follows:—

"* * * The third objection was, that the medical

* The subsequent statute 9 and 10 Vic., cap. 84, is merely explanatory and confirming the former.

certificate by the surgeon did not follow the form given in Schedule E. of the statute, as he is not stated to be a member of the Royal College of Surgeons, and his residence is not added, it being contended that the confinement was therefore unlawful, and consequently the order for maintenance made without jurisdiction. But we are of opinion, that the confinement did not become unlawful by reason of this irregularity in the form of the medical certificate. The examinations show that all the substantial facts necessary for sending a pauper lunatic to an asylum existed. It was not contended that the surgeon was not in fact qualified, or that his residence was not known; and as he appears by the examination to be the surgeon of the union to which the appellant parish belongs, the contrary is to be presumed. The keeper of the asylum ought to have required a certificate according to the form in Schedule E., before he received the pauper, and incurred responsibility by omitting to do so, under the 51st section; but after he had received her with the imperfect document and the confinement had begun, we think it was his duty to continue that confinement till the lunatic should be discharged. In *Re Shuttleworth*, the Court refused to discharge a lunatic brought up by *Habeas Corpus*, on account of defects in the certificate for confinement under the 8 and 9 Vict., cap. 100, and held the confinement lawful, though the provisions requiring the form of the certificate are the same in both statutes. * * * As all the objections fail, the order of sessions is confirmed."

This decision is important, as showing, in conjunction with the one on the 8 and 9 Vict., which refers to lunatics *not* paupers, that when a patient is *de facto* confined on sufficient grounds, and all the substantial requirements of the act fulfilled, the Court will not hold the detention illegal on account of trifling informality; but on the contrary, consider it to be the duty of the owner of a lunatic asylum to retain such person in confinement until properly discharged. At the same time medical men who have the care of the insane should remember that the "responsibility" they incur in taking a patient under a wrong certificate is nothing less than a "misdemeanor," and it is quite possible to imagine the most upright practitioner placed in a very awkward situation by an oversight of this description. Considering that the parties who *give* the certificate are wholly uninterested in the matter, it is probable enough that instances of such inaccuracy are not few; and not long since an instance came before the public where a patient had been confined for several years without a proper certificate having been obtained. The case we have brought before the notice of our readers shews that the transaction alluded to was as free from legal, as it was from moral guilt; but, considering how easy it is, by keeping a copy of the certificate given above, and comparing it with every writing sent, to prevent even the smallest inaccuracy, we think that our medical brethren who have the care of the insane, would do well to see that the minute requisitions of the act are always, as far as they concern themselves, strictly complied with.

Reviews.

On the Identity or Non-identity of Typhoid and Typhus Fevers. By WILLIAM JENNER, M.D. London: Churchill. 1850.

THE pathological problem which Dr. Jenner here essays to determine has long been a *questio vexata*, and has recently given rise to not a little discussion on the opposite side of the channel. In this country typhoid fever is, comparatively speaking, so rare, that the mind of the medical profession has not occupied itself much with the subject, and hence a more than ordinary interest should attach to the author's labours.

In examining the subject Dr. Jenner tells us that he has endeavoured carefully to separate well-ascertained facts from doubtful cases, and this he appears to have succeeded in doing as far as his means have allowed. It must, however, be conceded, that howmuchsoever of value we might be disposed to place upon his researches, his deductions would come home to our convictions with more force, had the premises from which they have been drawn been more extended. Sixty-six autopsies, after all, afford but a scanty field for the elucidation of so debateable a point.

We may premise that Dr. Jenner maintains the non-identity of the two fevers—typhoid and typhus. In order to develop this opinion, he has made a careful analysis of the above cases, dividing them into two groups, in one of which Peyer's glands were diseased, in the other healthy. In the first group we have twenty-three cases, in the latter forty-three. He then contrasts the various phases of the pathological history of these groups as follows:—

Previous state of health.—This was much the same in both classes.

Complexion.—Of "typhoid" patients, 80 per cent. were fair; of "typhus" cases, 30.7 per cent. only were so.

Sex.—The proportion was much the same.

Age.—The average age of the "typhoid"

patients was 22.08 years; the youngest 10 years, the eldest 36. Among the "typhus" cases 41; the youngest 8, the eldest 70.

Duration.—On this point the author is not able to offer any satisfactory data, from the difficulty of ascertaining the exact date of the commencement of the disease. The most he can do is to note the day of admission, and the supposed epoch of the malady at the time. But this must obviously afford but unsatisfactory evidence.

On the subject of the eruption of the two diseases, the author has the following remarks:—

The eruption in typhoid was papular, but not acuminated; the patches were circular, and rose-coloured. *They disappeared completely on pressure.* These spots were detected in all cases admitted before the fourteenth day of the disease, and the ordinary duration of each spot was three days. Fresh spots appear every day or two till the thirtieth day.

In typhus the eruption was never papular, and its characters varied with its duration. At first it consisted of dusky pink spots, of irregular outline. In two or three days the spots lost their elevation, and became darker; they faded, but were not obliterated by pressure. Some became converted into true petechiæ. These spots are more numerous and crowded than in typhoid. They usually appear from the fifth to the eighth day, and disappear between the fourteenth and twenty-first.

The above is a fair sample of the manner in which Dr. Jenner has endeavoured to fulfil his task, but we have as yet mentioned only a small portion of the labour he has bestowed upon it. The same careful analysis has been made of all the prominent symptoms during life, as well as of the appearances after death, in the two maladies, but for the details on these points we must refer to the original, as our space will only allow of a general notice of the manner in which the author sums up his cases. After recapitulating the differences which appear in the analysis alluded to, he observes, that he entertains no doubt that in all particulars the two diseases are distinct, on the following grounds:—

1. In the majority of cases the general symptoms differ.

2. The eruptions, if present, are never identical.

3. The anatomical characters differ, thus the lesion of Peyer's glands is never seen in typhus.

Without committing ourselves to the assertion that we are entirely satisfied that the author of this treatise has made good his case, we have no hesitation in recommending it to our readers as a model of scientific medical investigation. Although, as we have before said, the number of cases analyzed may justly be considered too small to allow of very definite conclusions, we are still content to receive them in better faith than the loose deductions of others, though ostensibly founded on double the number of cases.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

SEPTEMBER 5TH, 1850.

DR. FLETCHER IN THE CHAIR.

Calvarium of an old man, 68 years of age, after extensive Injury and Trephining.—By Mr. R. L. BAKER.

A calvarium, after having sustained extensive loss of its substance by fracture, trephining, and subsequent exfoliation, sixty-eight years ago. The space where the bone is deficient, in the lower part of the left parietal bone, measures three inches and a half by two and a half; it is filled up by a dense fibrous membrane, springing from the bony edges, and apparently formed in part by the dura mater, and in part by the external fibrous membrane. Both the dura mater and the epicranial aponeurosis were jointly adherent to the injured bone. The patient was a male, aged 78. He died of syncopal apoplexy, with atrophy of the heart. After the injury of the head he led a very active life, fifteen years of which were spent in the artillery service.

Perforating Ulcer of the Intestine in Fever.—By Mr. R. L. BAKER.

The ilium was perforated by an ulcer. There were signs of recent acute peritonitis, with effused lymph having a fæcal odour. The patient was a boy, aged 6. He had typhus, without intestinal irritation. For three weeks he was convalescent, but was suddenly seized with symptoms of acute peritonitis, and with diarrhœa. The diarrhœa ceased in four hours, but he died thirty hours afterwards.

Tumour of the Uterus, of Non-malignant form, Fatal by Profuse Suppuration.—By Dr. RUSSELL.

A tumour, the size of an orange, lay in the posterior wall, separated from the uterine cavity by the thickened lining membrane. Unhealthy suppuration had occured between the front of the tumour and the lining of the uterus, and the pus entered the uterus by a large sloughy opening in the lining membrane. The cavity of the uterus was much dilated; the os quite open. The cervix was healthy. The liver-cells were gorged

with fat. The right thigh and calf of the leg were occupied by one immense abscess, which communicated with the knee-joint, which was itself full of pus, the articular cartilages of the joint being almost destroyed. The large vessels were healthy. The tumour had precisely the character of the chronic mammary tumour of Sir A. Cooper.

By the Microscope.—It was found to be composed of a fibrous tissue, presenting the usual fine striation. By acetic acid the tissue became transparent, and exhibited nuclei and fragments of fibrillæ.

The patient was aged 55. She was married, but never pregnant. Catamenia had ceased, but had been regular previously. She was subject to occasional attacks of dysuria for the last seven years, and occasionally needed the catheter. Three months before her death she had an attack of purpura, from which she had nearly recovered, when at the end of the sixth week she had irritative fever, preceded by a rigor, and followed by synovitis of the right knee. Ten days after a profuse purulent discharge from the vagina occurred, quite suddenly, without a single sign of morbid action in the uterus; the discharge never diminished, the back sloughed from pressure, and the large abscess in the lower extremity burst a fortnight before death. The knee never improved under any treatment. She died, extremely wasted, six weeks after the vaginal discharge appeared.

Fungus of the Bladder, Diseased Abdominal Aorta, and Thickened Dura Mater of an old man, aged 96. —By Mr. Pemberton.

The fungus of the bladder sprung from the fundus, which it occupied. The pelvis and infundibula of the kidneys were dilated, and there were small cysts on the surface of the kidneys; the ureters were healthy. The arterial system, and most particularly the abdominal aorta, presented extensive calcareous deposits. The dura mater was remarkably thickened, resembling a piece of leather.

By the Microscope.—Characteristic cells were discovered in abundance in the fungous mass. The patient was a male, aged 96. He had bloody urine the last seven months.

Diseased Larynx, producing extensive Thickening of Pharynx and Abscess.—By Dr. Fletcher.

The patient died of inanition. The vocal cords of the larynx were thickened; the cricoid cartilage was softened, and pus exuded from it; the thyroid cartilage was healthy; the epiglottis thickened and ulcerated; the pharynx congested, thickened and ulcerated; abscesses had formed on each side of the pharynx, one of which communicated with the pharynx. The heart was closely contracted; the veins were prominent. The gall-bladder was much distended with bile. The coats of the stomach were atrophied; the duodenum was turgid with bile for a long distance. The intestines were nearly empty, and the colon much contracted, commencing suddenly and completely in the ascending portion, the gut being widely dilated just previously. The mucous membrane was healthy. The patient was a female. The disease was considered syphilitic. She became unable to take food after the formation of the abscesses, most of what entered the mouth escaped by one of the orifices.

Anchylosis of the Bone entering into the formation of the Ankle.—By Mr. Pemberton.

The tibia and fibula were connected by bone for an inch above the joint; the inner maleolus was attached to the astragalus, and the outer to a portion of the cuboid bone and to the os calcis; a large piece of the astralagus posteriorly formed a sequestrum; all the tarsus was united by a bony matter. The patient was a collier, aged 32, of strumous habit. He received an injury five years ago. There was great thickening around the ankle with ulcers. The limb was amputated, and the patient recovered very slowly.

Destructive Ulceration of the Cartilages of the right Knee-Joint.—By Mr. Pemberton.

The cartilage from the extremity of the tibia, and most of that from the inner condyle of the femur, was entirely destroyed, and the patella partially anchylosed. The joint was filled with pus, which had burrowed under the surrounding soft parts. The patient was a wheelwright, aged 30. He was affected with chronic synovitis three years ago. By issues and rest, a cure by anchylosis was expected, but treatment by a quack rendered amputation necessary.

Viscera in a Case of Diabetes.—By Dr. Fletcher.

The brain was healthy; the lungs were œdematous, congested and very friable; there were ragged cavities in their apices, and a little tubercular matter in the walls of the cavities; there was a small amount of yellow tubercle here and there through the lungs. The heart was large, flabby, and friable; *taches blanches* were found on the right ventricle. The liver was friable; the gall-bladder contained two ounces of bile the stomach presented spots of vascularity. The capacity of the stomach was normal, that of the intestines increased; the mucous membrane was healthy; the spleen diffluent; the head of the pancreas was twice its natural size; the duct large; the kidneys were large and soft; the cortical structure voluminous, highly vascular externally, an immense quantity of fat surrounded them; the ureters were normal; the bladder was one-third larger than usual. There was much fat in the peritoneal processes; oil in the contents of the stomach, and the hands of the operators were much greased. The patient was a pensioner aged 64, and was under observation two years. By diet of flesh and cruciferous plants, and Palmer's bread, he gained flesh; and the urine descended to specific gravity 1017-19 from 1030; and in quantity to three and half to five pints daily, from eleven pints; and Palmer's test, by liquor potassæ, did not detect any sugar. He had gained seven pounds in weight at the end of nine months. On leaving the hospital, he again declined: renewed

treatment was again *more partially* successful during the last month. He complained of pain in his chest, emaciated and sank very rapidly.

Gelatiniform Disease of the Ovaries.—By Dr. Russell.

The left ovary was entirely connected with an enormous tumour, enclosed by a thick membrane, which sent prolongations into its interior. The tumour was formed in chief part of a gelatinous looking tissue, composed of fluid, entangled in a meshwork of very delicate membrane, from which in time the fluid all drained away; and of cysts of all sizes, formed by the same delicate membrane, containing a like fluid, and also a fine areolar tissue, in small quantity. The fluid was nearly clear, limpid, strongly albuminous, in parts yellowish, in parts of a deep blood colour, tinging the general tissue with the same hue. But a considerable portion of the tumour was quite different in character, being composed of dense white matter, part crumbly like tubercle, part diffluent; this portion also contained transparent cysts of small size, and the limpid fluid from the general mass deposited sediment similar (under the microscope) to this dense matter. This tumour occupied most of the abdominal cavity, the viscera having been pushed aside by it; it adhered to the parietes, but not to the intestines, and was attached to the uterus by a pedicle formed of the healthy ligament. A small tumour of the same character was connected with the right ovary, which was itself converted into a small cyst, with dense walls. The uterus and all the other viscera were healthy. The abdomen contained much clear brownish-yellow fluid.

By the Microscope.—The dense white matter, whether forming the tumour or deposited from the fluid, consisted of cells, mostly approaching the spherical shape; the largest the 1-1800th of an inch, but most were much smaller; they contained a nucleus, had a sharp outline, a mottled character, and rather a dense tissue, the double outline being only visible in a few. There were some large cells, and collections of oil globules in cells, and free oil globules also. The liver was gorged with oil. The patient was aged 45. She had two children. Her health began to decline in July, 1848, commencing with diarrhœa and irregular menstruation. She improved by change of climate for a year, her menstruation continuing irregular; diarrhœa then returned, and continued at short intervals, often quite incontrollable. The stools were pale. She declined very gradually, but her countenance wore the aspect of malignant disease only for the last three weeks. Emaciation became very great. A month before death she had a sharp attack of peritonitis. Fluctuation was distinguished in the abdomen early in the last year of her life, but no tumour was distinctly felt till six months before death, probably in part from constant tympanitis. She had lost relations of phthisis. She died July, 1850.

October 3rd, 1850.

MR. W. H. PARTRIDGE IN THE CHAIR.

A protracted case of Chest Disease; late Development of Cavities in the Apices of the Lungs; scattered Tubercles; Sudden Death from Pulmonary Hæmorrhage.—By Dr. Russell.

The tissue of the lungs were generally very dense, and of an iron-grey colour; miliary tubercles were disseminated throughout, but had nowhere coalesced. Dense friable nodules, were scattered through the lungs, some appeared, on section, made up as it were of grey granulations; others were more uniform in texture. There was a very large cavity in the apex of each lung, in the right occupying almost the whole upper lobe; the cavities were free from anfractuosities, and were sparingly lined with lymph in patches; large tubes opened into them. A second cavity in the left apex, was quite filled with blood, and seemed the source of the fatal hæmorrhage; the trachea and primary bronchi contained much blood, but particularly the large tube leading to this cavity. Both lungs were capped with very dense false membrane; the bases of the lungs were loaded with diffused blood. The auricles of the heart were much dilated and hypertrophied; the tricuspid orifice was very large. The liver was free from fat. There were ulcers in the intestines. The patient was a female aged 29, a burnisher. She had suffered from chest symptoms for ten years. Her chief symptoms were cough, with mucous expectoration; dyspnœa was the most prominent symptom; it steadily increased, and at last quite prevented her taking exercise. She fell into an anæmic condition. Up to within six months of her death repeated examination failed to detect any disease in the lungs. Her symptoms then grew worse, diarrhœa came on, and after rather profuse hæmoptysis on two successive days, she died suddenly, with a gush of blood from her mouth. Her catamenia had ceased for the last year. She inherited consumption.

Strumous Disease of the Testis; originating in Gonorrhœal Irritation.—By Mr. Pemberton.

The disease had affected the left testis; it was of double size. A firm, yellowish-white, tubercular matter occupied the place of the proper tissue; the epididymis was quite distinct, it contained strumous matter. The brain was soft; copious milky serum was in the ventricles and between the membranes; the arachnoid was thickened. The patient had been a footman, aged 21. The disease followed on gonorrhœa six months ago, and was improving by treatment, when he died unexpectedly in a typhoid state.

A very protracted case of Chest Disease, the patient becoming Anæmic, and dying with scattered Tubercles and large Cavities in the Apices of the Lungs.—By Dr. Russell.

Both lungs were universally and most powerfully adherent, their tissue was very dense and firm, of an iron grey colour, with copious intermixture of black.

Miliary tubercles, less opaque than usual, were scattered through the upper lobes, but had nowhere coalesced. There was a moderate-sized cavity in the right apex, with a horizontal series of smaller ones just beneath, communicating with each other. The left upper lobe was hollowed by one enormous cavity, with ragged tails of pulmonary tissue hanging into it; there was a second beneath it. Some firm nodules, having a granular section, in the left lower lobe. The cavities had no lining, the coal-black pulmonary tissue being exposed; they were opened in extracting the lungs. Dense false membrane capped each lung. The large bronchial tubes were hypertrophied. Liver universally adherent to the diaphragm. The intestines adhered in several places. There were no tubercles nor ulcers. The patient was a brush-maker, aged 60. He had chest symptoms for twenty years; a winter cough for several years, with expectoration; and dyspnœa, gradually increasing, for some years. He recovered less completely from his later illnesses, emaciated, and fell into an anæmic state. His dyspnœa increased. His death was hastened by diarrhœa. The cavities were not indicated three months before death. Expectoration was not very abundant. His parents were asthmatic, but there was not any consumption tending in the family.

Phthisis, running a slow course, with symptoms of Debility and much Hysteria; large Cavities in the Lungs; scattered Tubercles.—By Dr. Russell.

Miliary tubercles were thickly scattered through both lungs, but had nowhere coalesced. The intermediate tissue was free from condensation. There were large cavities in the upper part of both the lungs, one only containing a thin, half-purulent fluid. Both lungs closely adhered by their apices. The intestines were healthy. The stomach and its mucous membrane were thickened and coarse. The liver-cells contained some fat. The patient was a female, aged 34; ailing twelve years. Her cough began two years and a half ago. Her decline was very gradual. Her symptoms were often disguised, and aggravated by hysteria. She had gastralgia and painful menstruation, with aggravation of her symptoms at her menstrual periods. Her bowels were irregular, constipated, or violently relaxed. She had hæmoptysis, and was of a consumptive family.

Obstructive Disease of the Mitral Valve, with Atrophy of the Muscular Parietes of the Heart.—By Mr. Bindley.

The mitral orifice was much obstructed, and narrowed by the thickening of the inner margins of the valves, and by calcareons deposit; and there was a layer of lymph in the lining of the left auricle. The heart was atrophied, small, and flaccid, with thin walls and rather large cavities. There was some soft lymph upon the auricular appendages, and turbid serum in the pericardium. The patient was a female, aged 50. She had cardiac disease for three years, and acute rheumatism thirty years ago. Dropsy commenced six months before death. Towards the close there were some slight attacks of pericarditis. She died comatose, the dropsy having diminished.

A Remarkable Cyst Expectorated.—By Dr. Russell.

A cyst an inch long, with a pedicle attached, resembling the stomach of a small animal, was expectorated by a middle-aged man, in a slight feverish attack. The cyst was distinctly vascular, but had collapsed when shewn to Dr. Russell. The patient quite healthy.

Uterus with Appendages, after adhesion of the Placenta and Puerperal Fever; Death fourteen days after Delivery.—By Mr. Bindley.

The cavity of the uterus was large; its internal surface was congested, and covered by thick dark fluid; a thin layer of placenta, decomposed, adhered. The sinuses did not contain pus, and were free from inflammation; the external surface, and the appendages were covered thickly with lymph. The right ovary was tumid; some of its vesicles were enlarged. The general peritoneum was inflamed and soft and adhered slightly to the viscera; some soft lymph had been effused. The liver was superficially softened. There were two quarts of fluid in the peritoneum, containing lymph and pus, and half a pint of reddish serum in the right pleura, with injections of the membrane. The skin was of a yellowish tinge. The patients's age was 37; she had seven children. She was delivered of a seven-month's child; the labour was natural, the placenta adhered but was readily separated, and there was little hæmorrhage. Low fever set in in a few days, with suppresssion of lochia and of milk; there was diarrhœa with pale stools and bilious urine; also tympany but little tenderness, and towards the last, pleurisy of the right side took place, jaundice occurred within thirty-six hours of death, and she died fourteen days after delivery. The attack could not be traced to contagion.

Perforating Ulcer of the Stomach.—By Mr. Hoskins.

The perforation was in the anterior wall of the stomach, a few inches from the cardiac extremity, it was of the cardiac extremity; it was of the size of a sixpence, with thick abrupt edges; the mucous membrane of the organ was thickened and very vascular in some places, but free from any other ulcer. The liver was not adherent. There were two quarts of sero-purulent fluid in the abdomen, and lymph had been deposited upon the intestines. The patient was a girl aged 14. She had been ill for a month with gastralgia, increased by food but not by pressure. She had occasional sickness and nausea, and her appetite was variable; she also suffered from constipation; she never had menstruated, and had a decidedly anæmic appearance. The symptoms of perforation occurred suddenly, after perfect relief from treatment. She died within sixteen hours.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

TUESDAY, FEB. 11, 1851.—DR. ADDISON, PRESIDENT.

On the 8th of January, a "Case of Cæsarian Section" was read by Dr. West, followed by some remarks on the peculiar sources of danger attendant on the operation. At the conclusion of these remarks Dr. Lee entered into a history of the operation, to which he is strongly opposed, and at the instance of Dr. Murphy the debate was adjourned to the above date, when the following was read, entitled,—

A Case of Cæsarian Section.—By Henry Oldham, M.D.

The subject of this case was a rickety, deformed girl, aged 23, unmarried, pregnant with her first child, and seven months gone in gestation, when first seen by Dr. Oldham. On examination, the pelvis was found to be reduced to two inches in its conjugate diameter, and the uterus was much anteverted.* The membranes were punctured for the induction of premature labour, in a few days after she was seen, September 23rd, 1850. On the following morning, the left arm was found in the vagina, but labour did not come on until nine A.M. on the 26th. In twelve hours the os uteri was dilated, and then some attempts to deliver her were made. The child could not be turned; but by drawing down the protruding arm, which, from commencing decomposition, soon gave way, and pressing the abdomen from below, the head was brought over the brim, and was at once perforated. For four hours the crotchet was employed both inside and outside the head, the bones of which were completely torn up, but without drawing it through the brim. At this time, a new impediment was found to have arisen, from the descent of the right hand and a foot, by the side of the collapsed head, into the pelvic brim; and, on watching the effect of labour-pains, all these parts were felt to be squeezed together in the narrow inlet of the pelvis, each preventing the other's descent. It was attempted to bring down either the foot or hand, but only the slippery tips of each could be touched, and they could not be moved. The patient had now been seventeen hours in labour, and it became a question for serious consideration and consultation, whether she would be able to sustain the necessary efforts for her delivery, and whether it would not be for her benefit to perform the Cæsarian section before exhaustion came on, which at length was determined on. The operation was performed by Mr. Poland, without difficulty, and with little hæmorrhage, the patient being under the influence of chloroform. The incision, five inches long, was slightly curved, and a full-sized seven months' fœtus was removed, and afterwards the placenta and membranes. For two days the patient did well, but then exhauston came on, and she died. While she lived, she was kept under the influence of opium, and was sustained by simple cold drinks. On post-mortem examination, there were some slight traces of peritonitis near the uterus. The external opening was closed, and its edges adherent, but the uterine incision was gaping. The larger omentum was indurated and inflamed, and so drawn across the uterus, above the incision, as to prevent any discharge from the latter organ escaping into the peritonæal cavity. Two practical questions were suggested by this case. 1st. What was the best plan to attempt to follow out in the delivery at first. 2nd. Were the complications such as to justify the Cæsarian section. With respect to the first, two plans of treatment might be adoptod: 1. To induce labour and deliver by craniotomy; 2. To allow her to go the term, and then perform the Cæsarian section. In determining in favour of the former, the author was guided by the great probability—with a conjugate diameter of two inches—of being able to deliver with the crotchet, and he considered that his inability to do so, arose from the complex presentation. With reference to the second, he was induced to have recourse to the Cæsarian section, from a conviction that the patient would probably sink under the prolonged efforts at delivery; and a case was related which occurred in the lying-in-charity at Guy's, under Dr. Ashwell, where a woman, with a far less contracted pelvis died undelivered, after the powerful and sustained efforts to relieve her. It was remarked that the girl had but a feeble constitution, which would ill support so hard a trial of its powers, and the condition of the vagina was particularly noticed as retaining the marks of early age, being structurally weak and easily lacerable, and most unfavourable for a long craniotomy operation. Under these circumstances the Cæsarian section offered a speedy and sure, instead of a prolonged and doubtful delivery. It was not yet forbidden from exhaustion, or any signs of inflammation; on the score of suffering it contrasted most favourably with the persistence in the use of the crotchet; and, upon the whole, it was judged to offer a better chance of ultimate success. The curve in the incision was suggested to catch the outline of the muscular fibres on the inner surface of the uterus, and so favour the closure of the wound. The scanty hæmorrhage during the operation was in a measure accounted for by the uterus being at the seventh instead of the ninth month, by the placenta being attached to the posterior wall and the uterus being opened low down towards the cervix, where the veins were less developed. Chloroform was said to be a gain in every way, and the after-treatment by opium appeared satisfactory.

The abstract of Dr. West's paper, read at the last meeting, was read, and immediately afterwards Mr. Wren got up to address the meeting. The President, however, reminded him that Dr. Murphy had moved the adjournment of the debate at the last meeting, and to him was due the privilege of commencing on the present occasion.

Dr. Murphy had moved the adjournment of the debate with great reluctance. Adjourned debates in that Society were seldom desirable; but in the present instance the adjournment would be of advantage, because it was impossible at the last meeting to answer Dr. Lee on the spur of the moment. Dr. Lee had come down to the Society with a written document, prepared with great care, and referring to facts which it was impossible at the time to analyze fairly or to answer with effect. He (Dr. Murphy) hoped, however, to be fortunate enough now, by an examination of the facts and arguments brought before the Society, to put the question fairly before the fellows. It would be in the recollection of the Society that Dr. Lee in the communication referred to had professed to give the history of the Cæsarian section. He quoted Guillameau's ill suc-

* The skeleton pelvis was exhibited.

cess and Mauriceau's consequent condemnation of the operation, which he described as being at once *inhuman, barbarous, and cruel.* He showed the effect of Mauriceau's opinion upon the operation, which was silenced not only in France, but in England, Mauriceau's great work having been translated by Chamberlen. The operation was subsequently reviewed on the Continent, not in consequence of any change in medical opinions, but because of the opinions of the Clergy. They held that the child had a soul to be saved as well as its mother; and inasmuch as the Romish Church required for that purpose a certain rite to be performed while it lived, they could not reconcile to themselves the frequent destruction of the unbaptized infant. Dr. Lee then brought before the Society a table of the results of the Cæsarian section amongst British practitioners, and casting a doubt on the authenticity of the cases of Mary Donnelly and Mr. Browler, arrived at the conclusion, that in British midwifery no single well-authenticated instance was on record of a mother recovering after the performance of the Cæsarian section. Dr. Lee then drew a parallel between the advantages of the Cæsarian section and the induction of premature labour in cases of deformity, and having given a history of the introduction of the latter into the practice of midwifery, proved its superior value to the Cæsarian section. The gist of Dr. Lee's argument amounted to this. Why did not Mr. Wren, who had charge of his case from the fifth month, having been warned by the presence of what appeared to be rheumatism, great difficulty in walking, and other symptoms, detect the presence of a deformed pelvis in his patient, and induce premature labour? Dr. Lee then alluded to the case which was under the care of Dr. Rigby and Mr. Skey, and inquired why premature labour was not also induced in that case? Lastly, Dr. Lee quoted a case of Dr. Simpson, occurring at Cupar. Dr. Simpson had seen the patient previously to the labour, and had given it as his opinion that, in consequence of the very contracted state of the pelvis, the Cæsarian section was the only mode in which delivery could be effected. When labour came on, Dr. Simpson was sent for, a distance of thirty miles, but before he reached Cupar the woman had been delivered by the natural efforts. This excited great amusement, and, as the report in the *Lancet* stated, Dr. Lee sat down amid cheering and roars of laughter from all sides. Now he (Mr. Murphy) respectfully protested against the principle that a Society like that should be made the medium of personal attacks upon our brethren in the profession, because such attacks naturally led to replies, the replies are answered, and retort and recrimination are the result, so that our discussions, instead of being confined to the real questions at issue, became more like the angry altercations of a mere debating club.

The PRESIDENT certainly did not consider that Dr. Lee had been dealing in personalities at the last meeting, or he should have stopped him. Dr. Lee was dealing, as he had a right to do, with individual opinions.

Dr. MURPHY admitted the distinction drawn by the President; he knew he would not intentionally tolerate personalities; but still he (Dr. Murphy) contended, that unjust reflections cast upon the practice of a professional man were a most serious personal injury to him. They should not be made without just grounds, and were most inconvenient in such a Society as this; they tended to draw us away from the real subject under discussion. He would, however, say no more on this point, but again return to Dr. Simpson's case, which Dr. Lee had very imperfectly stated. From the account given by him there was no distortion of the pelvis, no reason why such an operation should be resorted to, and that delivery by the natural efforts should have been expected as a matter of course. He (Dr. Murphy) held in his hand Dr. Simpson's account of the case—a case which that gentleman considered to be unique, and one to which he (Dr. Murphy) had seen only a similar instance in the Dublin Lying-in Hospital. Now, first, with regard to the pelvis in this case, he would beg permission to read Dr. Simpson's account of it:—"Early in March I visited Mrs. D—— along with Mr. Wiseman, Dr. Graham, and Dr. Grace. I found fully borne out the correct description which had been previously given me of the excessive deformity of the pelvis. The sacrum was straight above, so that the promontory did not probably encroach on the brim;" (here Dr. Lee stops in his account of it;) "but its inferior extremity was strongly and abnormally curved forward. In front the walls of the pelvis felt doubled and collapsed together, and the outlet, which was the only part that could be very accurately examined, was exceedingly deformed and diminished in size. The transverse diameter was particularly contracted. I found it impossible to introduce two fingers between the tuberosities of the ischia." Such then, being the pelvis, how was it possible that a child could be forced through it by the natural efforts? The description of the child resolves the enigma:—"The infant had been dead for some time *in utero*. It looked nearly its natural length; and as it lay extended on the table, it measured eighteen inches and a half from the crown of the head to the heel; but its limbs and body were thin, lank, and atrophied, and its weight was only three pounds three ounces. Its head appeared very large and disproportionate in size, and indeed had been considered hydrocephalic. This seeming increased volume, however, was not the consequence of effusion, but the result of putrefaction. The encephalon was in a dissolved and semi-fluid state; and as the head lay on the table, it was extended and flattened out laterally and superiorly, as if it consisted of a bag or bladder, half filled with liquid or semi-liquid contents; and such, in fact, it really was. In all, the bones of the arch of the cranium were separated from their attachments, and floated about in the dissolved and liquefied cerebral matter. The bones of the basis of the skull were also loosened, and more or less separated from each other—a rare occurrence. . . . The symphyses, even of the inferior as well as the superior maxillary bones, were loosened, and admitted of free motion."* So that it would appear from this description, so minutely detailed, that not a single bone of the cranium was joined together, and the child of course readily passed through under such circumstances. So much for the case of Dr. Simpson. He would now refer to the case of Mr. Wren and Dr. West. Dr.

* Case of Delivery, by J. Y. Simpson, p. 12, 13.

Lee inquired—"Why was not premature labour induced at the fifth month?" He (Dr. Murphy) would put the question to Dr. Lee—"On what grounds should it have been done?" There was no outward sign of deformity; the difficulty of motion was not so great as to lead to the suspicion of the presence of mollities ossium. This patient, the day before the commencement of labour, had actually stood up and assisted in hanging some curtains, so that there was no ground to suspect such deformity as was met with. The Society will also recollect that this was a first pregnancy; and the most eminent authorities laid it down as a rule that the practitioner had no right to induce premature labour in a first pregnancy, as no one can tell beforehand the exact amount of disproportion that might exist, or that the pelvis would not admit of delivery of the child by the forceps. In this present case Dr. Murphy would defy any one to know beforehand that it would be a case in which the Cæsarian section would be required. Dr. Lee himself admitted that such was the rule of practice, because he claims to be the first who broke through the rule; only twelve years ago, in 1838, he for the first time induced premature labour in a first pregnancy, and claims the merit of originality for this operation. Mr. Wren, then, only acted on the rule generally laid down, and on this ground, as well as others which he had stated, the Society would at once acquit Mr. Wren of the charge which had been made against him, of want of professional knowledge in allowing the case to go on to the full term. But to return to Dr. Lee's history of the Cæsarian section. He never heard a more ingenious way of getting through a question than that pursued by Dr. Lee. In fact, he had gone quite beside the real question at issue; which was not between the induction of premature labour and the performance of the Cæsarian section, for no one would resort to the latter when the former could be employed. The induction of premature labour is an operation as much superior to craniotomy and evisceration as it is to the Cæsarian section; and he would ask Dr. Lee how it was that, premature labour being so safely and easily performed, he had enumerated one hundred and twenty-seven crotchet operations, and had induced premature labour in only six of them? He put this question with great reluctance, in order to point out one of the inconveniences that must inevitably attend the mode of discussion that Dr. Lee had thought it right to take on this occasion. The real question at issue was the relative value of the Cæsarian section and craniotomy in certain cases of greatly contracted pelves, cases in which delivery is sometimes impossible by the ordinary means, and in others attended with such difficulties, in the attempt to deliver by the crotchet, that the danger to the mother is as great as in the Cæsarian section. The first case of this kind—one of malacosteon—he (Dr. Murphy) would quote from Mauriceau. His twenty-sixth Observation—a most remarkable one, because this was the case given to Chamberlen, to deliver with his newly-invented forceps. This woman had been eight days in labour. On the 4th day Mauriceau saw her, and found that he could not deliver her. Having ordered remedies then popular, to bring on and increase labour-pains, he returned three days afterwards, and having carefully examined her, found that he had not room to move his fingers in the pelvis, much less to use instruments to deliver her. A student of Mauriceau suggested the Cæsarian section; but no, Mauriceau would not hear of it. He would rather allow the woman to die undelivered than undertake such a proceeding. Fortunately, Chamberlen came to his relief. He tried his forceps when the uterus was in a state of gangrene, and of course it was said that all the mischief—rupture of the uterus, &c.,—was caused by the forceps. He (Dr. Murphy) believed no such thing. It was the first case of mollities ossium, in which even Mauriceau could not effect the delivery. Another case of malacosteon is related by the eminent Hamilton,* the case of Mrs. Scott, who was brought into the Edinburgh Hospital. Labour commenced at three A.M. "At six the pains increased so prodigiously, both in frequency and strength, that there was the greatest reason to dread, during every pain, a rupture of the uterus." An examination being made, no part of the child could be felt; but subsequently, the head being just felt above the brim, it was unfortunately determined to wait a few hours, and in the interval the uterus was ruptured. Mr. W. Barlow had a case of mollities ossium, which died undelivered of ruptured uterus. Mr. Dunlop another. Mr. Ridgeway a third, who was sixty hours in labour; the vagina torn, and died undelivered.† If we pass from these to modern authors, Dr. Meigs relates a case, (I am not sure that it was mollities ossium,) in which labour began on the 14th of June, 1831. A consultation of the most eminent men was held on the 16th, when Dr. Physick opposed the Cæsarian section. Dr. Meigs undertook craniotomy, and was from half-past ten P.M. to four A.M., endeavouring to extract the child. He renewed these attempts at intervals during the whole of the following day, and at length, on the third morning, after the patient had been given an opiate, and slept a little during the night, he succeeded. This lady recovered, and was afterwards twice delivered, by Mr. Gibson and Dr. Fox, by the Cæsarian section, with perfect success, of living children. Such is the evidence of the result of extreme contraction in the pelvis; and the last he shall quote is Dr. Lee himself. In his clinical Midwifery, Dr. Dee relates the case of Mrs. Jarvis, In January, 1830, she was delivered by the crotchet with extreme difficulty. On July 11, 1832, again delivered at the full term with great difficulty; premature labour was not yet induced. But on the third occasion, June 1833, abortion was induced at the fifth month successfully. Again, Feb. 12, 1835, at the beginning of the seventh month, also successfully. But the fifth time, Jan. 19, 1836, Dr. Lee again tried, when the patient was at the end of the sixth month of pregnancy to induce premature labour, "the os uteri was, however, so high up, that he could not reach it with the point of the finger, or introduce the catheter, to perforate the membranes." On Feb. 12, Dr. Lee again tried, and again failed, "partly in consequence of the forefinger of the left hand being nearly deprived of sensation and the power of motion from a dissection wound. Ergot of rye was then tried unsuccessfully,

* Outlines of Midwifery, pp. 285, 287.

† Hull's Appendix to Baudeloque's Memoirs, p. 150.

and at length, March 24th, Dr. Lee, having had an instrument made for the purpose, succeeded in perforating the membranes. The pains began on Friday the 25th, and continued to Wednesday the 30th, when Dr. Lee feared that it would be necessary to have recourse to the Cæsarean section."* Such, however, was not the case, because, at last, Dr. Lee succeeded, after immense difficulty, in extracting the child—and what was the result? the woman died twenty-four hours afterwards, of ruptured uterus. This was the only case of malacosteon that Dr. Lee had met with in practice. These were the kind of cases that, in the spirit of fairness, should be compared with those in which the Cæsarian section was performed. He (Dr. Murphy) might go into the details of cases showing similar difficulties in cases of rickets, pelvic tumour, &c., but time will not permit, the casts on the table of the Society will speak for themselves. He (Dr. Murphy) maintained, therefore, that when we were so uncertain of saving the mother's life by craniotomy, in such cases we were bound to consider the life of the child, and to give it the chance of being saved by the Cæsarian section; and before sitting down he would entreat the Society to examine with Dr. West into the causes of failure in this operation, and ascertain whether it is possible, by an improved knowledge, to render it more secure to the mother.

[To be concluded in our next.]

Foreign Department.

PROCEEDINGS OF THE FRENCH ACADEMIES.

ACADEMIE DE MEDECINE.

A DISCUSSION on the powers of *Arsenic in Intermittent Fever* arose on the occasion of a memoir by M. FUSTER. This gentleman expresses his belief that pernicious intermittents, however rebellious to quinine, will yield to the arsenical treatment, and states that he has never observed any of the injurious consequences usually laid to the charge of this medicine.

Dr. ARAN read a paper "On *Local Anæsthesia*," especially in reference to the comparative merits of the various known anæsthetic agents.

M. RENDU related a "Case of Foreign Body Impacted in the Larynx." As a boy, aged 5 years, was playing with a haricot bean in his mouth, he suddenly cried out, and was seized with urgent dyspnœa and convulsive cough; these symptoms soon abated, but reappeared in the evening with such intensity that on the eighth day it was necessary to perform tracheotomy. The opening made, the suffocation ceased, but nothing escaped. It remained open for fifteen days, and then closed spontaneously; the closure was followed by the reappearance of suffocation, but in a minor degree. One day, being seized with a violent fit of coughing, the bean was expelled, after which the child recovered.

* Lee's Clinical Midwifery. No. 146-150, 1st edition.

ACADEMIE DES SCIENCES.

AT this Assembly among other memoirs was one by M. BOURGUIGNON, "On the *Contagion and Treatment of Itch.*" As the result of his study of the subject he informs us:—

1. That there is no incontestable instance of the transmission of itch from the horse to man; every such supposed instance on examination exhibiting the true acarus of the human subject.

2. The same may be said of the dog-itch. It does not follow, however, that these eruptions in the lower animals may not give rise to cutaneous eruptions in the human subject, though not to true scabies.

3. As the result of actual experiment, the author determined the converse to the above proposition to be true; the acarus of scabies will live in the skin of the lower animals, but does not produce scabies.

In a subsequent part of his essay M. Bourguignon details the results of his experiments on the treatment of itch.

1. Frictions with simple oil destroy the acarus, but do not kill the larvæ of the insect. 2. Frictions with oil and sulphur kill both insect and ova, but give rise to considerable cutaneous irritation. 3. Frictions with oil and gunpowder were equally fatal to the insect, but produced eruptions almost as troublesome. From these and other experiments the author finally concludes that many different topical applications are equally efficacious in destroying the itch insect, but he gives the preference to sulphur ointment and the sulphureo-alcaline ointment of Helmerick, and these he asserts will cure the disease in forty-eight hours, if the patient during that period is anointed from head to foot every twelve hours.

The following prizes were decreed:—

To M. Jobert de Lamballe 2500fr. (£100) for his treatise on "Plastic Surgery."

To M. Guillot 1000fr. for an improved lithotrite.

To M. Morell Lavallee 1000fr. for his "Essay on Hernia of the Lungs."

To M. Herpin 1500fr. for a work on "Epilepsy."

To Dr. Delesianve 1000fr. for a work on "Epilepsy."

To M. Vrolik 1000fr. for a work on "Teratology."

FRANCE.

Syphilitic Muscular Retraction.

This is the name given by Dr. Notta, (*Archives Générales*, Dec., 1850,) to one of the later consequences of the syphilitic poison. The muscles chiefly affected are the flexors; the extensors, according to the author's experience enjoy a complete immunity. In all his cases, the upper limbs were the seat of the disease, and the right arm more frequently than in the left. For this reason the author thinks that muscular action may be a predisposing cause.

The proximate cause of the affection is syphilis, but in order to ascertain whether it could be referred to rheumatism, the author interrogated his patients. It

appeared in the result of his inquiries that none were the subject of rheumatic pains either before or during the attack of muscular retraction. In most of his cases the author had some difficulty in assuring himself of the pre-existence of primary symptoms, but out of six cases he found no difficulty in gaining the admission of secondary accidents in four. The retraction of muscles appears late in the category of the consequences of syphilis, and appears allied in time to the appearance of what are known as tertiary phenomena.

The commencement of the retraction was preceded by pains in the affected limb in five cases. It progressed very gradually, almost insensibly; the affected muscle, the biceps for instance, becomes shortened, so that the arm cannot be extended as usual. The muscle is neither tumefied nor altered in form. The skin remains perfectly natural in appearance.

No pain accompanied the attempt to flex the affected limb, but if it was extended forcibly it gave rise to considerable suffering in the tendinous portion of the muscle. Pressure did not give rise to pain in any case when made over the fleshy portion of the muscle.

Left to itself the disease may remain stationary, or proceed until the forearm is completely flexed upon the arm. It is not a dangerous affection in itself, but as an evidence of the syphilitic poison, it must always be regarded with interest. According to the author, it differs from the syphilitic retraction described by Ricord, as well as from the syphilitic affections of muscles alluded to by Vidal and M. Bouisson, in which the retraction is a symptom only of a distinct tumefaction—of the "tumeur gommeuse," while in the disease in question the retraction is the disease itself.

The treatment adopted by the author and with general success, is that adapted to consecutive symptoms, consisting of the iodide of potassium and mercurial frictions. He also derived benefit from blisters over the painful points.

GERMANY.

On the Urine in Pneumonia.

Dr. Redtenbacher (*Zeitschrift der k. k. Gesellschaft der Aertz zu Wien*, Aug., 1850,) gives the following as the result of a patient investigation of the questions:—1. What is the relation of the inorganic salts to the specific gravity of the urine? 2. Is there any intimate connection between the variation in the salts and the increase and duration of certain diseases?

1. The quantity of inorganic salts is not subject to great variations, so that they do not exercise any great influence on the specific gravity of the urine; it is the organic constituents—urea and uric acid—which chiefly affect its density. Urine of high specific gravity may contain a small quantity of inorganic salts, while a tolerably large amount may exist in urine of low specific gravity.

2. The quantity of chlorides in the urine has a direct relation to the intensity of the inflammation in cases of pneumonia. When the urine of a healthy person is treated with nitrate of silver, after being acidulated with nitric acid, the copious precipitate of chloride of silver shows the presence of a considerable quantity of chlorides. If the urine of a patient labouring under pneumonia be examined, a normal quantity of chlorides will be found at first; this gradually diminishes as the inflammation advances, until, when hepatisation is perfect, the chlorides entirely disappear, so that nitrate of silver does not even produce a cloudiness after long standing. When the inflammation, or rather the hepatisation, again recedes, the chlorides re-appear, and continue to increase as the disease advances towards cure. This diminution and re-appearance of the chlorides in pneumonia has been constantly observed by Dr. Redtenbacher, in upwards of eighty cases; and further, the smallest quantity of chlorides always accompanied the most intense inflammation, and the rapidity or slowness of their decrease or increase was in constant relation to the rapid or slow course of the disease. The re-appearance of the chlorides constantly accompanied the retrogression of the inflammation; their presence in the urine, indeed, often preceded the signs furnished by percussion in denoting incipient recovery.

It is true that, in typhus, acute rheumatism, and capillary bronchitis, the chlorides are diminished in quantity; but this decrease is not constant, nor does it appear at any certain period of the disease. In tuberculous infiltration, the chlorides are present in normal quantity, but diminish for a short time under a fresh addition of infiltration.

It might be objected, that the chlorides in the urine are chiefly dependent on the culinary salt taken within the food; but if this objection were of any force, they would be diminished in all diseases in which less food is taken, which is not the case. Besides, one-half of the patients with pneumonia had, throughout the whole course of the disease, taken drink acidulated with hydrochloric acid, yet the same phenomena were manifested, and there were no chlorides in the urine, when the disease was at its height.

It must hence be concluded that the removal of the chlorides from the urine during the course of pneumonia belongs essentially to the disease, and that they must be disposed of in some other manner.—*London Journal of Medicine*, December, 1850.

General Retrospect.

PRACTICAL MEDICINE AND PATHOLOGY.

Communication between the Stomach and exterior of the Abdomen.—By Dr. Robertson.

Isabella Davidson, aged 36, was in good health up to 14, when she became subject to darting pains in the epigastrium, which were increased by pressure, and recurred at intervals for seven years, accompanied by flatulence, costiveness, and eructations. At the age of 25 she first observed an elastic tumour between Poupart's ligament and the short ribs, which often

shifted its place, and finally disappeared after an attack of diarrhœa. In the year 1842 she again noticed a small tumour in the left side of the epigastrium, which steadily increased till it reached the size of an orange. This also disappeared, but in its place remained a dark spot, the size of half-a-crown. Her general health now began to suffer.

On the night of October 22, 1844, while washing some clothes, she felt the spot give way and fluid trickle down. She immediately stripped, when she found the contents of her stomach escaping. She swallowed draughts of milk, which rushed out of the opening.

She was attended to by Dr. F. Douglas, of Kelso, and by the end of January, 1845, the opening had completely cicatrized. Early in 1846, however, the cicatrix became red, and the fistula was re-established. It again cicatrized, and again re-opened in June, 1847, since which time it has remained open. Her health is tolerably good, but she is obliged to remain much in bed.—*Edinburgh Monthly Journal*, Jan., 1851.

Tincture of Sumbul in Hysteric Epilepsy.

By Dr. Pettigrew.

The author gives the following case, in which there was an hysterio-epileptic condition, combined with amenorrhœa, in which the effects of sumbul are said to have been miraculous:—

A female aged 21, diminutive, idiotic in expression, had never menstruated, was the subject of an epileptic seizure daily or oftener. She took ten drops of the tincture of sumbul three times a day. She began on the 20th of June, 1850.

July 2nd.—She had had two fits on the 29th, and one on the 30th, none since. She walks more steadily, intellect improved.

17th.—The intensity of the fits has diminished, not becoming unconscious; is stronger. Dose increased to twelve drops.

30th.—Has had four fits but much milder in character.

August 13th.—Has not been unconscious since last report; answers questions briskly; walks steady; and is altogether a different being.

Dr. Pettigrew does not adduce this case as a cure, but considers that the drug afforded great relief under most unpromising circumstances.—*Lancet*, Jan. 25.

Disease of the Pancreas—Diagnosis.

By Dr. Fearnside.

After detailing two cases of obscure abdominal disease, in which, after death, the pancreas was the organ chiefly affected, Dr. Fearnside offers the following remarks in diagnosis:—

The earliest phenomena in both cases were the gradual failure of the general health and faulty digestion. To this succeeded *deep-seated pain in the epigastrium*, aggravated a few hours after food; but this he observes may be due to a concomitant irritation of the mucous membrane of the stomach. *Gastrorrhœa* was present in both cases, but as the pancreas was diseased to such an extent as to prevent secretion, he justly supposes this symptom to be due to vitiated action of the mucous membrane of the stomach.

In one case *ptyalism* was a prominent symptom, and has been noticed in other cases of pancreatic disease. The tongue was *pale and clean* in both cases; the appetite variable.

In one case, *abdominal pulsation* was present. This is a symptom much insisted upon by Professor Siebold, when coexisting with other signs. The urine did not assist the diagnosis. *Emaciation and anæmia* were marked symptoms. From a comparison of these symptoms the author concludes, that though none are in themselves pathognomonic, the reunion of several affords strong probability of pancreatic disease.—*Medical Gazette*, December 6, 1850.

SURGERY.

Severe Fracture of the Os Frontis without symptoms of Compression.—By B. Sealy, Esq., M.R.C.S.

James Taber, aged 11, of Bishopstone, Wilts, received July 29, 1850, a severe kick on the forehead from a cart horse. On seeing him at 9 o'clock in the evening, about two hours after the accident, he was found partially insensible from concussion of the brain, but on rousing him he could answer questions rationally, quickly however, relapsing into his former semi-conscious state. On examining the head the author found a semi-circular scalp wound above the frontal sinuses, exactly in the centre of the forehead, corresponding with the shape of the horseshoe, with the convexity downwards, and about four inches in length, from which there had been much hæmorrhage. There was extensive fracture of the skull, a portion of the frontal bone being driven to the depth of more than half an inch, forming a cup-like cavity, the floor of which was about an inch long and three-quarters of an inch wide, entirely denuded of covering. The sides of this cavity sloped inwards, so that the brim was considerably larger than the floor. The fractured portions were of an irregular shape and firmly imbedded. There were no symptoms of compression; vomiting had taken place once, and he passed his water freely. Gave him Hydrarg. Chlorid., gr. iv., and applied cold-water dressing to the wound. When left alone in bed, the boy lay very still in a kind of stupor, but breathing regularly and quietly.

July 30th.—The author saw him at eight o'clock this morning, with Mr. Hind, of New Swindon. He had passed a quiet night; been sick once, after drinking some water; bowels not open; pulse regular; skin cool; he is, apparently, quite recovered from the shock of the blow; complains of severe pain in the head, and screamed much when touched. A projecting piece of bone was removed, and after a few days the case progressed satisfactorily.—*Ibid*, Jan. 18.

New Instruments for the Cure of Stricture.

These are the invention of Mr. Wakley, jun., and consist of—

1. A catheter, thirteen inches in length, of a very small size, slightly curved at the extremity; the stem quite straight, and having at the end a worm, for the reception of the screw of the directing rod.

2. A small thumb-slide, (removable at pleasure,) screwing closely upon, and acting as a handle to, the catheter.

3. A steel rod, which passes into the catheter as far as the screw, at which part both are united by two or three turns of the rod. The rod makes an addition of five inches to the length of the catheter. The rod and catheter combined form the index-rod, or director, for the metallic and elastic tubes.

4. Of the silver straight tubes, there are nine of graduated sizes: the first is only one size larger than the index-rod, and the others regularly increase in circumference; the last, or No. 10, corresponding with that number of the ordinary bougie. These tubes are all of a conical shape at their distal extremities, and are so constructed as to fit the mouth of each tube with extreme exactness at the surface of the index-rod. They thus slide with the most perfect ease along that guide, and being directed by it, if the rod be in its proper situation, the tubes cannot take a wrong course, or make a false passage, but must pass through the stricture.

5. There are also three *elastic tubes*, composed of a flexible metal, covered with elastic-gum fabric. This combination gives to the instrument very considerable strength, without rendering it clumsy or bulky. The extremity of each of these flexible tubes has the same form as that of the silver tubes, and fits with perfect accuracy the surface of the index-rod.

The mode of using these is as follows:—

First, introduce the catheter, as gently and with as much care as possible, completely through the contracted part of the urethra into the bladder; having done this, withdraw the stilet, and the surgeon having satisfied himself, by the escape of the urine, that the instrument is in the bladder, insert the smaller extremity of the steel rod into the catheter, and having secured it, by making two or three turns of the rod, remove the thumb-slide, and then pass No. 3 silver tube upon the index-rod right through the stricture or strictures. In performing this operation, the passage of the instrument will be much facilitated by giving to the flanges a rotatory motion as they are held between the fingers and thumb. This tube being withdrawn, the others may all be passed in a similar manner, and in regular succession. The number to be introduced must of course be determined by the operator. After the last metallic tube is withdrawn, an important object is still to be secured—that of *keeping the command of a free urethra*. This is a point of considerable importance, and may be accomplished with the greatest ease, by passing one of the *elastic tubes* over the index-rod, as was done in the case of the silver tubes. One of the flexible tubes being now in the bladder, *the index-rod is to be withdrawn through it*; this may be done with the most perfect facility. The *flexible tube* may be left in the bladder, to serve the purpose of a catheter, and also to afford a safe channel or guide for the re-introduction of the silver catheter or index-rod.

Removal of the Cuboid Bone, with the two Outer Metatarsal Bones and Toes.—By Mr. Coulson.

The patient, aged 22, observed a swelling on the outside of the right foot, which became red and painful. In July, 1850, this was opened, and a cheesy matter removed. The wound continued to discharge, and it was ascertained that the bone was diseased. Mr. Coulson saw the man on the 17th October, when he found a sore on the right foot corresponding to the cuboid bone, from which there was a sanio-purulent discharge. The bone was felt to be carious, and as the patient was much weakened by pain and discharges, it was determined to remove the bone, and if the disease had implicated others, to perform Chopart's operation, or remove the foot at the ankle-joint. An incision was accordingly carried from beyond the wound posteriorly, along the outer part of the dorsum, to the extremity of, and around the small and next toes. The skin was dissected back, so as to expose the cuboid and metatarsal bones. These bones were disarticulated from the cuboid, and the latter from the os calcis, which was sound. The healing of the wound proceeded favourably, and the patient eventually was able to walk well. The disease proved to be scrofulous caries.—*Lancet*, February 1.

MIDWIFERY.

Rare Case of Complicated Parturition.

By James Gray, M.D.

The following case of protrusion of the head of the child through the recto-vaginal septum in a common head presentation, is interesting from its rarity:—

On the evening of February 26th, 1850, Dr. Gray was summoned to Mrs. Y., in her first labour. He found her with severe expulsive pains. Hearing the child cry, he examined and found as he thought the head partly born, and covered by the membranes. A more careful investigation showed that the os externum was thrust upwards and forwards, the perineum greatly distended, and the anal orifice dilated, exposing its mucous membrane to the depth of an inch. The head presented in the second position, and the membranes were entire. The next pain stretched the perineum still further, without affecting the vaginal orifice. While endeavouring to guard against rupture of the perineum, the author felt something give way, and soon a child's hand protruded from the anus; the pains increasing, the perineum was momentarily expected to give way, but by great care this was prevented, and in about half an hour the external parts relaxed, and the head came through, the hand and arm at the same time being further propelled in their unnatural direction. As the shoulders were delivered, the author contrived to push the arm back within the rectum, and it was speedily made to issue with the rest of the body, *per vias naturales*.

On examination of the parts the rent was found to be a little above the verge of the anus, but the contraction of the rectum had reduced it to a mere fissure. No treatment was required beyond cleanliness.—*Edin. Monthly Journal*, January 1851.

TOXICOLOGY.

Case of Arsenical Paralysis.—By Dr. Corton.

This is a case resembling those published by Sir C. Hastings, for which reason, together with the comparative rarity of their occurrence, we insert the subjoined account:—

Charles Wilson, 41, Swede seaman, was admitted into hospital, December 1st, 1849. He states that, accidentally, about five months ago, he swallowed some arsenic, which had been laid aside for the purpose of killing rats; that remedies were promptly used, which counteracted the primary effects of the poison; felt perfectly well for seven days afterwards, was then attacked at night with a violent cramp in the index finger of the right hand, successively invading the other fingers, and lastly the thumb, then attacking the other hand in the same manner, and finally the feet, the pain in the hands subsiding as the feet became affected; that the whole duration of cramp was about thirty minutes, after which he fell into a sound sleep, which continued until morning; that when he awoke he felt free from pain, but on attempting to rise, was surprised to find that he had lost the use of the affected parts, and was in fact perfectly helpless; and that this paralysis has continued unchanged to the present time, accompanied with a feeling of heat and numbness, which invaded the upper extremities, from the tips of the fingers to a point about three inches below the elbow, and the legs, from the toes to a point a little below the knee. Has also had lancinating pains in these parts, regularly commencing about five P.M., and continuing until midnight.

Now, paralysis and nocturnal pains continue as above stated. He can neither feed himself, nor stand alone when placed upon his feet. Has dryness in his throat, and great thirst. Nothing remarkable about his general aspect or symptoms. He had been subjected to a variety of treatment before admission. Has been mercurialized, and taken iodide of potassium. Anodynes, warm baths, good diet, were prescribed.

July 14th.—Has used for a time sulphate of quinine. Strychnine, in ordinary doses, and electricity, were persevered in for a considerable time. He has slowly and pretty steadily improved. About January 7th he first began to walk with a shuffling, unsteady gait; he soon after could use his hands in feeding himself. Now he can walk quite well, grasps the hand with some firmness, but cannot yet button his own clothing. Has had no pain for some time, save in the approach of stormy weather, when peculiar painful sensations are perceived in his fingers. On January 10th his urine was found to contain arsenic, but in May all traces of the poison had disappeared. He was discharged relieved in July.—*New York Journal of Medicine.*

Correspondence.

THE APOTHECARIES' ACT OF 1815.

To the Editors of the Provincial Medical and Surgical Journal.

Gentlemen,—Although I most cordially agree with your respected correspondent, Mr. Bree, in his remarks on the degrading and pseudo-dishonest practice of charging patients for medicine a sum which is properly due for time and skill, I must beg to be allowed to point out an error or two which, in common with many others, he has fallen into, respecting the Apothecaries' Act, and the administrators of that act. Mr. Bree speaks of the Act of 1815, as tending to perpetuate the union of the science of medicine "with a trading corporation." He says that,—"By the Act of 1815 the licence to practise the art and mystery of medicine could only be obtained by passing an examination before a board selected from a trading corporation." And, further, he asserts that,—"By that act the principle of charging for medicine was legalized; and the practice of the great body of general practitioners *since that day*, has been to charge a certain sum for the medicines taken by their patients," &c. He further alleges that the expediency of charging for medicine was created by a "legislative blunder." In all these statements Mr. Bree echoes the belief of the junior members of the profession generally, and it is because the belief *is* general that I take the liberty of saying that the prevailing impression on all these points is erroneous.

1. The Society of Apothecaries is not "a trading corporation." There does exist, it is true, a joint stock company, dealing in drugs, the shares of which are only to be purchased by the members of the Society of Apothecaries in actual practice; but the purchase of these shares does not constitute membership. There are many members who are not shareholders. Nor is it necessary that the Board of Examiners should be shareholders. It may be composed entirely of members who have no connexion whatever with the "trade."

2. The principle of charging for medicine cannot fairly be said to have been legalized by the Act, for not only was it previously legalized, but it has been decided in the courts of law that by the Apothecaries' Act the principle of charging for *attendance* has been legalized; and, in fact, the powers of this much-abused Act have deprived us of all excuse for charging for drugs, inasmuch as by it we are enabled to recover for medical attendance.

3. So far from the operation of the Act having changed the custom from charging for skill to charging for drugs, the very reverse has taken place. Before the act of 1815, if we except the charge for "journeys," in country practice, no apothecary or general practitioner ever dreamed of making any charge for visits or attendance, but only for medicines, midwifery, and surgical operations. But now the number of those who never think of charging for drugs, except with disgust and loathing, is, happily, increasing every year. Thanks to the Act of 1815, and to the improved tone of the medical profession generated by its operation.

4. Your correspondent states that "the Apothecaries'

Company has done much in raising the standard of medical education in spite of the Act of Parliament." This again is not quite correct. What would the Apothecaries' Company have accomplished *without* the Act? Clearly *nothing*. Probably Mr. Bree intended to say, "In spite of the imperfections of the Act." This is most true; and it is equally true that "as a body they have not advanced medical science a single step." It would have been strange indeed if they had. Those members of this despised Society who have had the honour of advancing medical science (and they are not a few in number) have of course either accomplished their task by individual effort or in connexion with the members of some Society established for the promotion of the special branch of science to which their attention has been directed. Examining bodies do not constitute the advanced guard, but rather the rear-guard, of the medical body. Their appointed business is not to speculate in improvements, nor to take the lead in discovery; but to see that all the members of the medical body are acquainted with the established principles of the science. The standard of their examinations should, therefore, be raised from time to time as the science advances. This has been done in a most exemplary way by the Board of Examiners appointed by the Society of Apothecaries. They have raised the standard of medical attainment very considerably, as is acknowledged on all hands; and while I would give them credit for the sober zeal with which they have executed this great work, I must still maintain that the Apothecaries' Act of 1815 has alone given them the power to effect it.

In conclusion, I beg to disclaim the expression of any opinion on the much-vexed question of Medical Reform, and even to express my regret that a controversy which will prove I fear more fruitful in discord than in any other result, should have been again, in spite of your Editorial wishes, thrust upon your attention. No legislation can keep mean spirits and low-minded men out of the profession. No Act of Parliament can raise the relative condition of the sedimentary portion of the profession. Let us not be deluded into the hope that any British Legislature will ever consent so to restrict the practice of medicine as effectually to put down quacks or ignorant practitioners. This will never be done; and the wonder is, that any thinking man should cherish so hopeless an expectation. The Act of 1815 was never intended for this purpose. Its "imperfections," as they are called, were carefully-devised evasions. The provisions of the Act were well canvassed by the medical practitioners of the day, and although they succeeded in erasing many objectionable clauses, not one of them suspected that mere druggists, or quacks calling themselves druggists, were *intended* to be left with as full liberty to practise as before. But so it was, and so it will be in every future Act professing to restrict the practice of medicine, surgery, and midwifery. No effective restriction will ever be contemplated for a moment by those who have powers to effect it.

I am, Gentlemen, your obedient Servant,

TRUTH.

London, Feb. 22, 1851.

THE PUBLICATIONS OF THE ASSOCIATION.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—As you have lately alluded to the management of the *Journal*, can you inform myself and the other members of the Association when the Committee appointed at Hull to consider the publications of the Association are likely to make their report. It is to be hoped that their suggestions will be proportionate in value to the time occupied in maturing them. They have unquestionably a difficult task, but I trust they will agree upon some effective plan, for it is a melancholy fact that an Association comprising nearly two thousand members should be so barren in its productions. The old tale "parturiunt montes," &c., is singularly applicable. The fault, no doubt, is in great measure with its members; but I cannot help thinking there is some want of tact and energy at head quarters. Surely, from so large a body, one volume of "Transactions" in a year and one journal in a fortnight might be extracted containing matter of a higher standard and more useful stamp than that which usually emanates from our press.

I am one of that number who consider that the Association descended from its high position as a scientific body when it entered into the field of medical politics; and I think that when that subject becomes the Hamlet of the play we had better discontinue the performance.

May I be allowed to suggest the three following points to the consideration of the Committee:—

1. The propriety of using a varied type in the *Journal*, so that certain subjects, such as medical politics, &c., might occupy less space and a less conspicuous position.

2. The appointment of a foreign Editor, who, not content with prosy accounts of the meetings of the Academie des Sciences, and lengthy extracts from the *Gazette Mèdicale*, would give us a little of the *pith*, scientific and practical, physiological and pathological, from the German, Italian, and French journals and authors. I am sure there are many well-qualified gentlemen who would engage to do this for a fair remuneration. The extracts from English journals, &c., would of course be continued, also the reviews, though I would not suggest the one in your last number, on an "Address to a Medical Student," as an object of imitation.

3. The enlisting into the service certain gentlemen in the larger provincial towns, who would collect information, give the accounts of important operations and cases, and in various ways contribute to the efficiency of the publications. I do not conceive there would be much difficulty in this.

I am, Sir,

A FREQUENT READER.

February 8, 1851.

DR. MEREI.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—I beg leave to direct attention to a typographical error which I have met with in your last publica-

tion. At page 105 an extract is made from an article on "Convulsions in Children," which appeared in December last, in the *Edinburgh Monthly Journal*. The Christian and surname of the author, with whom I have the honour of being well acquainted, have been so altered and merged in one word, that it was some time ere the mistake was detected.

The name, as given by you, is Schopferei, a curious compound of Schoepf Merei. Dr. Merei is Fellow of the Hungarian Academy, late Professor of the History of Medicine in the University of Pesth, Founder and Director of the Children's Hospital at that place, &c., &c., &c.; and author of a comprehensive work on "Diseases of Children," of which we may in due time, it is to be earnestly wished, have the benefit of a translation into our own language.

I remain, Sir, your obedient Servant,

J. WHITEHEAD.

Manchester, February 24, 1850.

[The error arose with the combined assistance of our own printer and him of the *Edinburgh Monthly*. We have at least the satisfaction of knowing that foreign names do not undergo one half the mutilation by us that British names are submitted to by our foreign contemporaries.—Ed. Journ.]

Medical Intelligence.

APPOINTMENT.

Dr. W. H. Parsey, Assistant Medical Officer of the Devon County Lunatic Asylum, is appointed Medical Superintendent of the Warwick County Lunatic Asylum.

ROYAL COLLEGE OF SURGEONS.

Professor Owen will commence his annual course of lectures, in the theatre of the College, on Tuesday, the 4th of March next, and deliver twenty-four lectures on Comparative Osteology. Professor Paget will commence his course of six lectures on Tumours, on the 29th of April. Tuesdays, Thursdays, and Saturdays, at four o'clock, is the time appointed for the delivery. The interesting course of Microscopic Demonstrations, by Mr. Quekett, will terminate for the season on the commencement of the above lectures.

Gentlemen admitted members Friday, February 21st, 1851:—William James Broadwater, Canon Street Road, St. George's in the East; William Chaytor Beale, Kennington; Arthur David White, Winchester, Hants; Edward Bishop, Kirkstall, Yorkshire; Wm. Frederick John Turner, Horton, Gloucestershire; Joseph Brady, Dewsbury, Yorkshire; John Deane Baker, Oakhill, Somerset; John Emlston, Helperby, Yorkshire; Chas. King, Hon. East India Company's Service, Bengal; Thomas James Vallance, Stratford, Essex; and Wm. Henry Sheeby, St. John Street Road, Islington. At the same meeting of the Court, Mr. Samuel Reginald Potter passed his examination as Naval Assistant.

SOCIETY OF APOTHECARIES

The following gentlemen were admitted members on Thursday, February 13th, 1851:—Charles Travers Mackin, and Lewis Thomas.

OBITUARY.

Feb. 8, at Gloucester, aged 70, Ralph Fletcher, Esq., many years Consulting Surgeon to the Gloucester General Hospital.

Feb. 22, at his residence, Banbury, Oxon, Caleb Clarke, M.D., in the 41st year of his age.

BOOKS RECEIVED FOR REVIEW.

Medicines; their Uses and Mode of Administration. By J. Moore Neligan, M.D., Edin, M.R.I.A., &c. Third edition. Dublin: Fannin and Co.

Dr. Rankings' Half-Yearly Abstract of the Medical Sciences. July—December, 1850. London: Churchill.

The London University Calendar, 1851

The Monthly Journal of Medical Science. Feb. 1851.

The Dublin Quarterly Journal of Medical Science. February 1851.

Pharmacopœia Nosocomii in Curam Morborum Cutaneorum, 1850. London: Highley.

On a remarkable effect of Cross-breeding. By Alex. Harvey, M.D. Blackwood and Sons, 1851.

Thirteenth Annual Report of the Suffolk Lunatic Asylum, 1850.

A Letter to the Right Hon. Sir George Grey, Bart, M.P., on some of the several relations of the Medical Profession. By G. Robinson, M.D., Newcastle-on-Tyne.

London Journal of Medicine. February, 1851.

Letters on the Laws of Man's Nature and Development. By H. G. Atkinson, F.G.S., and Harriett Martineau. London: Chapman, 1851.

Prostitution in Relation to Public Health. By W. Acton, late surgeon to the Islington Dispensary. London: Churchill, 1851.

The American Journal of the Medical Sciences. Jan., 1851.

The Transactions of the American Medical Association. Vol. III., 1850.

TO CORRESPONDENTS.

Communications have been received from Dr. Tilt, Mr. Humphry, Mr. Ikin, Dr. Nelson, Mr. Banks, Mr. Kelson, Dr. Cooper.

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho. But all communications respecting the routine business of the Association should be forwarded to James P. Sheppard, Esq., the Secretary of the Association.

It is also particularly requested that all post-office orders should be sent either to the Treasurer or Secretary, who alone have the power of giving receipts.

A COURSE OF
LECTURES ON SURGERY,

DELIVERED IN THE

MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq.,

Downing College, Surgeon to Addenbrooke's Hospital.

Lecture XXX.—Cancers *(Continued.)*

Softening; curative and retrograding processes; review of the changes taking place in a part affected with cancer tending to show that cancer depends upon a morbid state of nutrition in the system and in the organ affected, and that it consists in an altered condition of the original tissues of the part together with an infiltrated exudation in which new products are formed; this view supported by reference to the circumstances under which cancer occurs, by its mode of extension from point to point, by its liability to affect various organs in the same person, and to return after extirpation; occasional localization of cancer; question of its capability of propagation by inoculation; some objections to the above view of the nature of cancer answered; reasons for thinking that cancer is not parasitical and not dependent on a morbid condition of the blood; simple tumours very rarely become malignant; liability of inflammatory products to assume the cancerous characters; similarity of scrofula and tubercle to cancer; important points of difference between them; age, sex, and temperament most liable to cancer.

Treatment of cancer; preventive measures: extirpation; circumstances under which it may be attempted; precautions to be observed: pressure.

The process of softening in cancer commences usually in the cellular element, and affects the fibrous stroma subsequently. It commences at several points, so that the section of a cancer in an early stage of softening, exhibits numerous cavities of irregular shape, containing a yellowish ichorous or semipurulent fluid, and separated from one another by tough opaque fibres. Subsequently the fibres are broken down and larger cavities formed, having ragged walls, with partially isolated bundles composed of softened and half-destroyed tissue hanging into them, or extending across them. The blood-vessels passing into the substance of the cancer are destroyed in the same manner as the other components of the tumour; not uncommonly they burst, permitting the effusion of blood, which coagulates, and gives a reddish-brown or yellowish tinge to the mass. Sometimes the effused blood quite fills up the cavities and obscures the original structure of the tumour, so that the whole mass may present the appearance of a sac filled with blood. This is rather a remarkable specimen; it contains several flat, circular, or oval cancerous ulcers upon the peritoneum lining the diaphragm. They present a peculiar appearance, being in their circumference a little raised above the rest of the membrane, while their centres are depressed and reticulated, in consequence of a number of little open cavities being left, from which, doubtless, the softened cells have been removed while the fibrous network remains.

So determinedly and unceasingly destructive is the progress of cancer, that it is a question whether it ever has a favourable termination—whether a cancerous ulcer ever becomes *permanently* healed over, or whether a cancerous tumour ever *completely* retires. So seldom does this take place, that for all practical considerations we need scarcely admit the possibility of its occurrence. Still there can be no doubt that an attempt at *partial* healing does not unfrequently take place in cancerous ulcers. I have seen partial cicatrization in scirrhous ulcers of the breast; and cancerous disease of the skin, now and then, like a spot of lepra, spreads at the circumference, and disappears at the centre, so as to present a hard, knotty, ringlike elevation, encircling a smooth shining plate of cicatrix. Again the scirrhous tubercles of the liver immediately under the peritoneum, which are usually flat on the outer surface, are sometimes indented or cup-shaped, with a raised, knotty, puckered edge, like the coagulum of inflammatory blood. A section of such a tubercle will generally show the centre part to be composed only of the fibrous skeleton of the cancer which has become contracted; the cell-structure, which we may suppose to have been originally contained in the meshes of the fibrous stroma, appears in such cases to have softened, and to have been absorbed without an extension of the destructive process to the fibres themselves. However, these are rather matters of pathological curiosity than of practical importance, for so few are the recorded instances of spontaneous cure in well-marked cancer, that we can afford our patient very little hope from the probable results of nature's efforts in his behalf.

Dr. Bennett, as I have already mentioned, describes those yellowish masses so often found in the substance of cancer, particularly in cancer of the testicle, to consist of shrunken, abortive, and disintegrated cells, mixed with much oily matter. He finds, also, that cancerous exudation sometimes becomes infiltrated with saline particles, thus undergoing in his opinion, a kind of calcareous degeneration, analagous to that which takes place in ordinary tubercle. Granting these changes to be of the nature he suggests, and admitting that a retrograding or even a curative process is thereby shown to be at work, we cannot derive much consolation therefrom, because the changes are always limited to *parts*, and those usually very small parts, of the malignant growth, and they seem to have little or no influence upon the general work of destruction which is going on around them. A few cells may become abortive, or portions of the tumour may undergo calcareous degeneration without the mass being less fatal or even much less rapid in its progress. Dr. Walshe regards these calcareous particles, which he says are occasionally though rarely found in cancer, as depending upon a degeneration of the fibrin of blood extravasated in the tumour.

To review briefly the changes that take place in a

part affected by cancer. We find in the first instance, that certain of the natural tissues of the part, more particularly the fibrous and areolar, are thickened, rendered coarse and tough, indeed altered much in the same manner as when they are the subject of chronic inflammation with effusion of lymph. This change has been exemplified by reference to the elongation, thickening, and ossification of the periosteal fibres, by the condition of the muscular coat of the intestinal canal, of the septa between the lobules of the mammary gland, and by other instances of a similar kind. At the same time a change of a contrary nature is seen to take place in the other and more highly organized tissues—the glandular, muscular, &c.; these become wasted, degenerated, and perhaps loaded with oily matter. Thirdly, there are infiltrated amongst the tissues, thus hypertrophied and atrophied to a greater or less extent, taking the place of the latter, and, it may be, in process of time, of the former also, a number of nucleated cells, nuclei, or granules. These, of which one or all may be present, in the same specimen, very scantily or very abundantly, are possessed of a power of generating other bodies of a like kind; but they do not ordinarily seem capable of advancing beyond the cell-stage of organization. In very many instances indeed they do not attain even to that stage, their developmental powers being limited to the formation of nuclei. The production of these bodies, added to the hypertrophy of the natural structures just mentioned, gives that increase to the size of the part which we call a tumour, and the rapidity of *its* growth is as a general rule proportionate to the rate of *their* development. I say that these bodies do not seem *ordinarily* to be capable of advancing beyond the cell-stage of organization, because it is possible that they do sometimes, by a further effort of development, contribute to the formation of the fibrous element of the cancer. However that may be, they soon exhibit a tendency to decay, which is shared by the other components of the tumour, and which leads to the formation and spreading of an ulcer in the manner I have described.

The several phenomena just mentioned, viewed in connection with those we have found to attend the formation of simple tumours, and more particularly with those accompanying the growth of warts, polypi, and the like, unquestionably combine to give great countenance to the opinion before hinted at, that the cancerous disease consists in, and depends upon, an altered or morbid condition of the nutritive properties of the part affected, in consequence of which the original tissues undergo certain modifications—hypertrophy or atrophy as the case may be—and new products are formed from the elements of the blood, having little capability of organization, and much tendency to decay. When the disease is least virulent, the natural structures are least altered, and the new products are fewest in number, the destructive processes are most tardy, and the other inveterate qualities of cancer are least manifested. Many of the cutaneous and mucous cancers as well as the malignant varieties of fibrous tumours, exemplify the truth of this statement. On the other hand, when the disease is more virulent, scarcely a trace of natural structure may be left, the new products abound so as perhaps to constitute almost the entire mass, the work of destruction is rapid, and distant as well as neighbouring parts are soon involved.

This opinion derives additional weight from the fact that cancer makes its appearance most frequently when, from some cause or other, the natural energy of the nutritive functions is diminished, between the ages of fifty and sixty, when the adult is beginning to lapse into the senile frame, after long exposure to anxiety, fatigue, or impoverished diet, after a lingering illness or a course of mercury. It is also most likely to appear in a part which has been the seat of some previous disease or continued irritation—in a cicatrix, an ulcer, or a wart; it is frequently traceable to a blow or a slight inflammatory attack, and it advances commonly with rapidity proportioned to the increasing debility of the sufferer. Perhaps the strongest argument of all is afforded by those cases of warty cutaneous growths, which, both in structure and qualities, seem to occupy an intermediate position between simple and malignant tumours. The gradual transition from common hypertrophy to cancerous disease, is so manifestly displayed by them in some cases, that it cannot be overlooked, and it furnishes most important evidence with regard to the question of the relation of malignant to simple disease.

The mode of extension of the cancerous disease from point to point, and from tissue to tissue, at the part affected, accords with the view of the nature of cancer just mentioned, at least as well as with any other theory, and corresponds with what we observe to take place in other diseases. In the healthy state of nutrition one tissue exerts no especial influence upon any other, the assimilative forces of each being manifested only upon the fluid elements of the blood that lie within its range, or that are received into its substance; but when a morbid condition has by any cause been induced at one part, it is communicated from that part to others in the immediate neighbourhood, radiating from the point first affected as from a centre, and spreading with a rapidity proportionate to its own force, and the ease with which the nutritive functions of the adjacent tissues admit of being disturbed. Thus an inflammation in the finger, excited by a wound, or arising spontaneously, spreads over the hand and arm, travelling furthest in the weakest subjects; and the cancer tubercle, overpowering in like manner the natural assimilative properties of the neighbouring parts, impresses its own qualities upon them, and spreads less rapidly it is true, but more surely than the inflammatory disorder. The exact cause of the *primary* aberration from the healthy standard must remain a mystery in both diseases; but having commenced they seem to advance in much the same manner. The more decided and inveterate progress of cancer, as compared with that of inflammation and other diseases, though constituting a feature of immense practical importance, is probably, after all, owing to a difference in the degree of its force, rather

than in the manner of its advance. Much has been said of its liability to affect the absorbent glands as an argument in favour of the theory which attributes the extension of cancer to the transmission of sporules by the circulating current, for it is supposed that these sporules are received into the absorbent ducts, arrested in the glands, and become there the germinating centres of fresh disease. Admitting that these sporules can find their way into the absorbent system, it is scarcely necessary to resort to the theory just mentioned for the explanation of the phenomena observed; for if a simple inflammatory ulcer is so often attended with inflammatory affection of the absorbent glands, it is no wonder that the more virulent cancerous disease is productive of corresponding results. We are equally ignorant of the *modus operandi* in either case; probably it is the same in both.

Further, the liability of cancer to return after complete extirpation, and to affect various organs in the same person, are features by no means at variance with the view we have taken. The fact of the existence of such a disease in any one part of the body, more particularly if it be of spontaneous occurrence, implies a defective condition of the nutritive functions, not of that part only, but throughout the whole system, for the several tissues and organs in each individual are very nearly balanced in their ability to resist disease, and their tendency to succumb to it; they resemble one another also in their liability to succumb to a particular kind of disease. In other words, the nutrition of the different parts of the body is conducted with nearly the same force, and is likely to show its defects in nearly the same manner. Thus in one person the organs are subject to acute inflammatory disorders; in another to slow tedious inflammations; in a third to such as we call scrofulous; in a fourth they fall at an early period into a state of atrophy or fatty degeneration, and the existence of such defect in one organ leads us to augur a similar condition of the others; in a fifth they become subject to cancer. Of course with cancer, as with any other disease, the existence of a particular local cause, impairing the nutrition of the part, and engendering the disease, such as a blow or long-continued irritation, renders us less apprehensive of the appearance of the malady in other parts of the body, and of its reappearance after extirpation. In such cases we are more willing to undertake an operation, for it is then, to a certain extent, though not entirely, a local affection. The fact that cutan ous cancers are less virulent and less likely to return after operation is, I apprehend, in great measure dependent upon their having been in so many cases induced by an external source of irritation.

Although the several organs and parts of the body are so nearly balanced in the energy of their nutritive functions, that the existence of cancer in one makes us apprehensive of its appearance in some other, you will, of course, suppose that the organ and region first affected are more likely to be the seat of fresh manifestations of the disease than any others. Thus separate scirrhous tubercles are very often developed in the vicinity of a breast which is the seat of cancer. A return of the malady is most likely to take place in or near the cicatrix resulting from the operation for the removal of cancer, and in undertaking an operation you, for the same reason, should excise the neighbouring parts as freely as you can. If the breast be the seat of the disease, you should not be content without removing the whole organ; if a bone, you should amputate at or above the neighbouring joint. I have sometimes been surprised at the limitation of cancer to the organ or region primarily affected. In the case of a woman, whose breast I removed on account of scirrhus rather quickly advancing, the disease reappeared after a few months near, though not in, the cicatrix; in the substance of, or in close contact with, the pectoral muscle. This was also completely excised, and she remained well for two years, when a lump formed on the cartilage of the second rib; it increased to a large mass, bursting through the skin, and involving the adjacent ribs and sternum. A careful examination after death disclosed no trace of disease in any other part of the body. In this case, then, cancer appeared three times in the vicinity of the same spot, at length running its fatal course without any other organ being involved, not even the adjacent absorbent glands. I remember, also, the case of a man in whom scirrhous tubercles commencing on one toe, spread up the same extremity to the groin, existing in great numbers on that limb, though we could not find a symptom of disease in any other part of the body. Analagous cases are by no means uncommon, and the localization of cancer in this way is certainly no less reconcilable with the view of its nature I have given you than with the theory which supposes the primary element in the disease to consist in some morbid condition of the blood, or with the theory which explains its extension from one part to another by the propagation of germs through the medium of the blood.

This latter view of the mode by which cancers spread is, of course, closely connected with the question of their propagation by inoculation or contagion. The whole evidence afforded by every-day observation and by experiment is completely adverse to the possibility of the communication of this disease by inoculation, with one solitary exception, and that is the often-quoted experiment of Langenbeck, who succeeded in inducing secondary cancerous tumours in the lungs of a dog, by injecting into its blood-vessels fresh cancer-cells from a tumour, while still warm, which had been removed two hours and a half previously from the humerus of a man. The experiment has been repeated with great care by Vogel, Valentine, Gluge, and others, but without success. It remains, therefore, to be proved more clearly that cancer-cells, when removed from the parent mass and lodged in a new situation, can retain their vitality and become the nidus of a growth. Even granting the probability of this, it is difficult to understand how they can, under ordinary circumstances, find their way into the blood-vessels so as to be transmitted to distant parts, for they are usually of considerable size, exceeding the one hundredth of a line in diameter.

Admitting, however, both these points, there remains the still greater difficulty of accounting for the first appearance of the disease in each particular case. Is it not far more probable that both the primary and secondary manifestations of cancer are due to the same cause which, like the causes of most other diseases, we can refer, in the present state of our knowledge, only to an aberration of the nutritive forces at the parts affected.

I am quite aware that the view I have given you is open to certain objections, and that it is rather hard to be reconciled with some of the phenomena of cancer—such as the very decided features of the disease, which seem in many instances to mark it out as distinct from all other pathological conditions, and which have induced persons to regard it, perhaps too exclusively and completely, as an affection *sui generis*. This difficulty I have endeavoured to smooth down in the preceding lecture, by showing that it has its points of similarity to other maladies, and that it is connected with them by certain intermediate affections, which present in different degrees the characters of simple and malignant disease. Secondly, the peculiar structure of cancer, so unlike, to the unassisted eye at least, any of the natural tissues or any other morbid products, has greatly favoured the idea of its consisting of some new parasitical growth, feeding upon the body and propagating species in neighbouring and in distant parts by the dissemination of germs. The microscope has done much to dissipate such a notion, by showing that all the elements of cancer correspond to a considerable extent with those of the natural tissues, and that its peculiarity consists chiefly in the mode in which those elements are combined together. It must not be forgotten, in relation to this point, that certain of the tissues of the part affected, in a hypertrophied or altered condition, have been shown to constitute an ingredient, probably a very important ingredient, in the cancerous growths. Thirdly, the uniform appearance of the cancerous tumours, formed in various parts and in totally different organs in the same individual, is, perhaps, the most forcible argument against the view I have been maintaining. It is, I think, weakened by the observation made in the last lecture, that the more highly organized tissues, that is to say, the tissues upon which the peculiarity of an organ chiefly depends, vanish away before the advances of cancer, or are metamorphosed, while the simpler tissues, or those more common to various parts of the body, alone remain and enter into the composition of the growth. These objections—and some others of less weight might be mentioned—are not, in my opinion, sufficient to counterbalance the arguments and probabilities in favour of the view before expressed, that cancer consists in part of an altered condition of the areolar and fibrous tissues of the organ affected, and in part of new products formed from the elements of the blood, possessed of little capability of organization and much tendency to decay. Both the altered condition of the original tissues and the infiltration of the new products, as well as the peculiarities of the latter, are, according to this view, due to some abnormal state of the nutritive functions of the organ which we cannot very well understand; but neither of the elements of the cancer are to be regarded as parasites any more than the blood-globules or natural formative cells are so considered.

These remarks on the pathology of cancer are opposed to the theory of the disease, which attributes it to some special change in the blood, nearly as much as to that which supposes it to consist of parasites. They show it to depend upon a faultiness in the processes by which the materials of the blood are converted into tissue, rather than upon a vitiated condition of the assimilative properties of the blood itself; that it belongs, in short, to the solid rather than to the humoral department of pathology. In a constitutional disease like cancer both solids and fluids, doubtless, participate in the defective condition, whatever it be, which engenders so disastrous a result; still the first and chief manifestation of the disease is presented by the solids, and I do not see that the mode in which that manifestation occurs affords a sufficient reason for referring the malady to any especial morbid change in the fluids. The qualities of the blood described by Rokitanski and others, to distinguish what they call the "cancerous dyscrasia," are very vague, and, for aught we know, are as likely to be the effect as the cause of the tumour.

It is a question of much practical importance whether a simple tumour is liable to be the seat of malignant disease. We often hear it adduced as an argument for the removal of a simple growth that though it may not be malignant at the present time it is likely to become so; and a very cogent argument it would be were there much truth in it; but I suspect that such an event is one of very rare occurrence, if we except the instances of cutaneous and mucous warts, to be spoken of more at length in the next lecture. The only case I have ever met with where there was any good ground for supposing that cancer had been engrafted upon a simple tumour was that of a woman who had long suffered under fibrous tumours of the uterus. One of these tumours of great size projected into the abdominal cavity, and in course of time became covered at one part by cancerous disease, which affected the whole surface of the peritoneum. In this case it certainly did appear that the malignant growth had extended from the peritoneal covering into the substance of the tumour at several places, and there were, nearer to the centre of the tumour, some isolated white tubercles, differing from the rest of its structure, and resembling the cancer found in other parts; but we could not be certain that these were really of cancerous nature. That lymph-formations and inflammatory exudations may become, and are very likely to become, the seat of cancer there is good reason to believe. Indeed a malignant growth often seems to extend itself, in great measure, by maintaining an inflammatory state of the surrounding parts; the lymph effused in consequence of such inflammation, being subject to the prevailing assimilative force of the cancerous growth, becomes likened to it, and is converted into the elements of cancer, instead of undergoing the transformations which

take place under ordinary circumstances and under ordinary assimilative influences. So, in like manner, lymph effused in any organ of a patient who is the subject of the cancerous diathesis is likely to participate in the morbid state, and to undergo the morbid transformation. Indeed it appears that the fibrin of the blood, coagulating within the vessels in such cases, may exhibit modifications of a similar kind. Thus, in a case, quoted by Dr. Bennett, of encephaloma of the stomach, mesenteric glands, and liver, Gluge and M. Nonat discovered cancer-cells in the clot of the right iliac vein, similar to those which existed in other diseased parts. The walls of the vein were smooth, and not red. Such instances are, however, rare; and further observations are required to confirm the correctness of this opinion.

I must say a few words with regard to the points of resemblance between cancerous and scrofulous diseases. These are so many that certain pathologists have regarded cancer as only a variety of scrofula, and *vice versa;* indeed it is the opinion of some of the most excellent of modern pathologists, both in our own country and in Germany, that the common tubercle is one of the varieties of cancer. To this opinion I cannot altogether yield assent, for, although there are many remarkable analogies between the two diseases, there are also, it appears to me, sufficient differences of an essential nature to induce us to retain in pathology that distinction which has the sanction of general experience.

Scrofula and cancer *resemble* one another, inasmuch as both consist in the infiltration of a new exudation-substance into the interstices of the texture of a part, that infiltration being attended with a wasting or degeneration of the original tissue; both have a tendency to soften and to ulcerate, causing a loss of substance in the affected organ, and leading to more or less extensive destruction of the body; both seem to be closely associated with, or dependent upon, a want of energy in the nutritive forces of the body generally, as well as of the affected organ in particular, so that the existence of either disease at any one part, leads us to apprehend its appearance in another; both affect all the organs and tissues of the body almost indiscriminately; each presents nearly an uniform appearance in whatever region it is found; and the one is often so much like the other, that it is scarcely possible, with the naked eye, to distinguish between them.

A cancer *differs* from a scrofulous mass in its greater inherent energy of growth; its more complete organization, which is evidenced by the formation of cells, of fibres, and of blood-vessels in its substance; its more complete independence of inflammation; its power of growth, of assimilating the adjacent fluids and tissues, and in its more determined progress. The scrofulous matter, as you remember, is composed chiefly of granules, hardly ever attaining even to the cell-stage of organization, and is dependent for its increase, not on its own assimilative power, but on fresh exudation, which is commonly the result of an inflammatory condition. It often falls into a quiescent state and is absorbed; or if it softens and ulcerates the disease does not generally go on spreading in the circumference, and the ulcer for the most part heals. Such important pathological and practical differences are, undoubtedly, quite sufficient to justify the separation of these two kinds of morbid products into distinct classes.

That tubercle should be ranked with the least inveterate of these two classes—that it is the form which scrofula ordinarily assumes in the internal organs, I have already expressed my opinion. True, it is the form of scrofula, most nearly approaching to cancer in its comparative independence of inflammation, and in its greater fatality; but the tuberculous mass possesses no higher organization than the scrofulous; it has no cells, fibres, or blood-vessels, except those which chance to remain in it from the undestroyed tissue into which it is infiltrated, and these diminish in number and disappear after a time, so that they cannot be regarded as proper elements of the tubercle, but merely as accidental constituents. Tubercles have no power of assimilation or of increase; they are fatal on account of their numbers, not, like cancer, in consequence of the energy of their growth. Each tubercle having softened, burst, and discharged itself, has done its worst; it leaves no spreading remnant behind, and the cavity produced by it will contract and heal, provided it is not maintained and enlarged by other tubercles forming in its walls and bursting into its interior. The non-existence of any cells or other elements possessing a capability of reproduction, constitutes an important point of distinction between tubercle and cancer, connected as it is with the inability of the former to increase in size, and to exert a destructive influence upon the surrounding tissues. A cancer grows by virtue of its own inherent force; a tubercle is enlarged by some extraneous influence depositing fresh material upon it. It may, I grant, increase in size a little, but no more, probably, than is accounted for by the softening and imbibition of fluid and other changes going on in it. Moreover, tubercle very rarely co-exists with cancer in the same individual, though it is a frequent concomitant with scrofula. Indeed the ages and classes of persons most liable to scrofula and tubercle, are found to enjoy the greatest immunity from cancer.

Cancer has been known to occur at every period of existence. Instances are not wanting, though these are rare, of its having been developed during intra-uterine life. The general impression that the disease rarely occurs in early life, seldom originates in old age, and is especially frequent in both sexes between the ages of thirty-five and fifty, has been shown by Dr. Walshe not to be quite correct. He finds from the examination of the returns supplied by the Registrar-General, that the mortality from cancer goes on steadily increasing with each succeeding decade until the eightieth year; after that period the results are liable to error. The influence exerted by sex on the development of cancer is very decided. The same author shows that the female population of this country is destroyed to about two and three quarter times as great an extent by cancer as the male. His experience leads him to coincide unequivocally with those observers who have remarked that women of high colour and sanguineous temperament are

more subject to mammary cancer than those of a different constitution. My own impression is that the same remark may be applied to the liability of that particular temperament to cancer in both sexes, and in other parts of the body; more particularly in the earlier periods of life. The young subjects of cancer whom I have seen have been, with few exceptions, dark-haired, and of rather florid complexion.

Cancer is a disease no less malignant in its resistance to treatment, than determined in its progress when left to itself. On this account we should be the more anxious to watch the circumstances under which it arises, and endeavour to adopt such preventive measures as are likely to ward off an attack in the persons who seem most liable to suffer from its inroads. We have found that it is most likely to occur towards the latter periods of life, and in those who have been subject to some distressing cause, such as long continued anxiety, an attack of illness, insufficient food, &c. It seems to be closely associated with a want of energy in the nutritive processes engendered by such circumstances; and the obvious inference is, that in all cases of the kind, a liability to the invasion of a formidable enemy should make us more active and persevering in our efforts to restore the general health, and to give fresh vigour to the natural forces of assimilation. Very often, it is true, there is no such preliminary or preparative stage that we can discover; the disease too frequently surprises us by laying hold with inveterate grasp on the young, the strong, and the apparently healthy, where we had not the slightest reason for suspecting its occurrence. In the earlier periods of life, more particularly, we have no chance of resorting to any preventive measures, because the presence of the enemy in the camp is always the first symptom to excite our apprehension; but in later years, especially about the age of 50 or 60, when the physical powers are beginning to decline, and when some indisposition or illness is very apt to linger about the system, we shall do well to be on our guard against the terrible malady, and should remember not to treat lightly those ailments which, though insignificant in themselves, may pave the way for one so formidable. There can be no question that a proper attention to the slight indispositions at this time of life, would often prevent that depression of the vital powers which terminates in the development of cancer, or in some equally fatal disease. The knowledge also of the fact that cancer frequently makes it appearance in a part which had been the subject of a blow, an attack of chronic inflammation, or any long continued irritation will suggest the removal of some of the local exciting causes no less than the endeavour to diminish the general predisposing influences.

When the disease has made its appearance, there is little hope of a remedy except by extirpation; and it must be lamented that the success even of this treatment is not proportionate to its severity. The removal of a cancerous tumour is so generally followed by its reappearance in the neighbourhood of the cicatrix or in some other part of the system, that surgeons of the greatest experience are commonly most unwilling to subject their patients to the pain and risk of an operation which is not likely to be ultimately successful in its results. Such experience coincides, I think, completely with the view I have given you of the pathology of cancer. For according to that view, it is not, even in its very first stages, a local disease, breeding germs and extending to distant regions by the diffusion of those germs, so that we might hope by exterminating the parent at an early period, to prevent the propagation of the species; but it is an altered state of the textures of a part, induced by a morbid condition of their nutritive functions, a condition which, in a greater or less degree, pervades the whole system; and the manifestation of cancer in one organ, unless it have been caused by some local irritation, is a tolerably sure evidence of the existence in other organs of a condition similar to that which has lead to such fatal results in the part first affected. At the same time, however, that I ask you to bear this view of the nature of cancer in mind, and more particularly ask you to remember the facts upon which it is founded, it is necessary that I should also remind you of the local qualities and the local influences of the disease, when speaking of the propriety of adopting any local means of treatment. For although cancer be a constitutional affection, and the result, in a great measure, of some particular state of the system, there can be no question that when it has once commenced it possesses the property of infecting the surrounding structures, and of inducing in distant parts, and in the system generally, that cachectic condition which is most likely to be productive of secondary manifestations of the disease. Moreover, it may have been excited prematurely in some one organ, in consequence of the nutritive functions of that organ having been lowered beneath the standard of the rest of the body. Of this we cannot always form a correct estimate, though the history of the case will often furnish valuable information to guide us.

In considering, therefore, the advantages derivable from operative surgery in the treatment of malignant tumours, we have to bear in mind the constitutional nature of the disease, the extent to which the local manifestation of the disease reacts upon the system, as well as the influence which it exerts upon the neighbouring glands and other parts; and, thirdly, the various exciting causes operating upon the part affected, and predisposing it in a peculiar manner to become the subject of cancer. It unfortunately happens that in individual cases the relative weight that should be attached to information derived upon each of these points is necessarily uncertain, and our opinion after all must be formed very much upon general impressions. As an ordinary rule, I think it may be said, that when there is a fair probability of removing the entire disease and a certain margin of the surrounding healthy tissue, without endangering life, we ought not to decline giving the patient the chance afforded by an operation. That chance is not sufficient to warrant any great risk of the loss of life; and, in my opinion, such formidable and dangerous procedures as amputation at the hip-joint, or removal of the superior maxillary bone, are not justi-

fiable in cases of malignant disease, unless there be some peculiar reasons for anticipating that the disease will not return in the wound or in other parts. Sufficient has already been said of the nature and pathology of cancer, to assure you that an operation is useless, or worse than useless, unless the entire mass be removed, for the remnant is sure to spread, and the patient is subjected to all the distress, pain, and danger, attendant on the use of the knife without having gained a single advantage over the enemy.

To this rule of operating when there is a good prospect of removing the whole tumour without materially endangering the life of the patient, there are, of course, some exceptions arising from the age or general cachectic state of the system, &c; moreover, it is seldom advisable to remove a cancer when the loss of so much skin would be involved as to leave a large open wound, which must be closed by the tedious process of granulation and cicatrization, for in such a case the disease is almost sure to return before the wound is healed. There are also some particular cases in which general experience would seem to show the inutility of an operation under any circumstances.

A recurrence of the disease in or near the cicatrix after the removal of a cancer is so disheartening, both to the patient and the surgeon, that the latter has not commonly the perseverance to propose, or the former the courage to submit to another operation. Nevertheless, I believe the same remark applies as in the first instance, viz., that we should again remove the tumour, provided we can do so safely and completely. In many instances unexpected success has followed these secondary operations, indeed I have heard it remarked by surgeons of much experience, that they are on the whole more satisfactory than the average of primary operations for the same complaint.

But, you may say, if the constitutional predisposition form so important and decided a feature in the pathology of cancer, why should we be at the pains of taking such summary steps for the removal of the local manifestation of the disease. To this, the best answer that I can give is founded on the fact, that the extirpation of the primary cancerous tumour, with due regard to the provisos I have mentioned, certainly does have the effect, in a great number of cases, of arresting the malady for a time, and of prolonging life. The respite, it is true, is too commonly but short, nevertheless it is an equivalent for the price the patient pays, which in these days of anæsthetic agents has been materially diminished. It would be an important point to ascertain whether the secondary cancerous tumours are more rapid in their progress, or more liable to infect other parts of the body, when the primary tumour has been removed by operation. My own impression is, that they are not so, but extensive careful observation is required to enable us to decide a question of this nature. In some cases the disease has not returned at all in the neighbourhood of the operation, but has affected a distant part, perhaps an internal organ, and the patient has been spared the greater pain and loathsomeness of an external cancer.

In planning and performing operations for the removal of cancers, it is particularly necessary to remember that these tumours are often freely supplied with blood, the surrounding vessels being enlarged in a proportionate manner; also that the morbid structure is generally continuous with the adjacent tissues; not separated from them by a capsule, or even, in some cases, by any well defined line. This, added to the fact that the adjacent tissues are often prematurely adherent together and indistinct, may embarrass the operator a good deal and render it difficult to make sure of removing the entire disease without interfering with large vessels or other important parts.

The prospect of cure afforded by an operation is very different in the different varieties of cancer. In the epithelial form, to be described in the next lecture, the cure is often complete, which is probably to be explained in a great measure, by the fact that this variety of cancer, affecting chiefly the skin and mucous membranes, is attributable to some local source of irritation, and that it does not consequently indicate a constitutional predisposition so strongly as the scirrhus, encephaloma, or melanoma. Of these, the last, I think, usually infects the greatest number of organs in the same individual, and is most sure to reappear after extirpation.

After an operation has been performed, we should endeavour to facilitate the healing of the wound and the speedy restoration of the patient to air and exercise. Of course, the remarks made with regard to the prevention of cancer are especially applicable to the circumstances under which we have so much reason to apprehend its return.

The use of strong caustics for the extirpation of cancer is confined to the skin, and will be mentioned in the next lecture.

There can be no doubt that the growth of cancer, more particularly of encephaloid cancer, is restrained in some degree by pressure; it takes place slowly in proportion to the depth of the tumour from the surface, and proceeds with greatest rapidity when, having destroyed one stratum of tissue after another, it bursts through the skin, and throws out a luxuriant vascular fungus. The observation of this fact suggested a trial of artificial pressure by bandage, or, what is far better, by the air cushion, as proposed by Dr. Neil Arnott. Where this treatment has been perseveringly followed it has been found in several cases to retard the growth of the tumour, and add much to the comfort of the patient; it is even reported in some instances to have caused the complete removal of tumours of the breast which had been decided by competent judges to be of cancerous nature.

Various medicines have been employed in the treatment of cancer; some with the view of arresting the disease, and others for the purpose of alleviating the patient's sufferings. For an account of the effects of these I must refer you to the elaborate treatise on cancer by Dr. Walshe.

ON THE

RIGHT MANAGEMENT OF YOUNG WOMEN

BEFORE THE FIRST APPEARANCE OF MENSTRUATION.

By E. J. TILT, M.D.,

Senior-Physician to the Paddington Free Dispensary for the Diseases of Women and Children, and Physician to the Farringdon General Dispensary and Lying-in Charity.

It has been so frequently admitted as an axiom, that on the right education of youth depends the peace of families, the prosperity of states, and the progress of humanity, that it would be only a truism to say the same of the education of girls; and yet, were I to ask whether we have been as skilful in improving the human race, as we have been in developing the instincts of animals, and in endeavouring to appropriate their capabilities to our advantage, no one would presume to say—Yes! It would seem as if we thought that the art of educating man had long ago been brought to perfection, for with but slight differences, the child is tutored as his grandfather, notwithstanding the change of time, the alteration of circumstances, and the boasted advance of civilization.

The task of maturing the body as well as the mind and the affection of the female child, so as to ensure health, is a sacred duty which devolves almost exclusively on the mother. It is not my intention to write a treatise on education, but being firmly convinced that many of the most serious diseases incident to women, are caused by the bad management of girls at this critical period of life, I shall proceed to embody the advice I have been frequently requested to give, with the view of awakening the attention of the profession to a subject of such importance.

During the stage of puberal development, nature is for some time attempting to inaugurate a most important function, and those efforts which should be assisted, are often frustrated by girls themselves, who—taken by surprise—are either in total ignorance or are insufficiently prepared to adopt such means as will favour its establishment, and ensure its due reappearance. If mothers, independently of professional assistance, are, from ignorance unprepared to give their daughters advice at this period, or withhold it from mistaken notions of delicacy, the most serious consequences may ensue, as is obvious from the result of a statistical inquiry in which I have been long engaged. In several hundred women I find that twenty-five per cent. were unprepared for its appearance; thirteen girls out of the twenty-five were much frightened, screamed, or went into hysterical fits; and six out of the thirteen thought themselves wounded, and washed with cold water. Of those frightened the flow was checked in seven instances, was never restored in three, and the general health of all was seriously impaired. Of those who washed with cold water, two succeeded in effectually suppressing the flow, which only reappeared after several years, and then at irregular intervals, and was never healthily established.

It may be said, that it is only in the lower classes that girls are kept in darkness relative to what is of so much importance: but this is perfectly groundless. The same bad management equally prevails in the middle and the higher classes of society. Girls in affluent circumstances and well educated, are, I know, often taken by surprise at the appearance of this function. Mothers who, in other respects, act judiciously, will not condescend so far to bow down to the infirmities of their nature, as to give the necessary advice to their daughters; but when the event happens, they are too often turned over to the management of an unmarried attendant. I have been also informed by a lady presiding over a large establishment of young ladies, that the pupils who are placed with her after the appearance of that function, are never properly prepared for the event, and that many are so ignorant of themselves, that it is extremely difficult to prevent their washing with cold water, in the endeavour to remove what they naturally view with feelings of disgust.

When girls—young though they may be—suffer habitually from headache, and when this is accompanied by dulness of intellect, dizziness, heaviness, and great tendency to sleep, it is most probable that menstruation is impending, particularly if these head symptoms coincide or alternate with pains in the back and lower limbs. Additional confirmation may also be found in the change which may be observed in a girl's character. If she no longer takes pleasure in the society of children, shuns companions of her own age, and finds in solitude charms hitherto unknown;—if uneven in temper, she is at times as usual—cheerful and expansive, at others cold, peevish, fretful, and even mischievous, but afterwards atoning for these inconsistencies by the most fervent expressions of tenderness;—if her eyes shine with unwonted lustre in mixed society, having lost the innocent confiding expression of children, who boldly dive into the depths of other eyes, because they know not of dangers to be encountered there;—in fact, when woman has become unto herself a mystery, the medical attendant should lose no time in advising the mother not to let her daughter be taken unawares, and to prepare her to expect what is the common lot of all her sex, so that its first appearance may neither be arrested by the alarm naturally felt at something hitherto inexperienced, nor by the dangerous application to which, in their ignorance, they may imprudently have recourse.

Here I must allude to the disastrous use of emmenagogues at this period of life, and to the question so often asked of the medical attendant whether it would not be judicious to give forcing medicines, so as to hasten the desired event. The following sad history, related by Dr. Dewees, a celebrated American physician, is the best answer that can be given on this subject:—"We too often call to mind, with bitter recollection, the fate of a most amiable interesting young creature, for whom we were requested to prescribe for the expected menses, but who had not one mark that could justify an interference, more especially as she was in perfectly good health. 'She was 15; it

was time;' and this was all that could be urged by the mother in favour of an attempt 'to bring down the courses.' We relied too much on the good sense of her anxious parent, and freely explained ourselves to her. She left us apparently satisfied with our reasoning, and we heard nothing more of the child for six months, when on being suddenly summoned to attend her, we found her throwing up blood in considerable quantities from the lungs, of which disease she died in a few days. The distracted mother told us that though she *appeared* satisfied with what we had said, she felt convinced we were wrong, and that her daughter's health required the immediate establishment of the menstrual evacuation. With this view she determined upon trying a quack medicine of some celebrity in similar cases. She gave it according to the direction, and in a few days her daughter became feverish, lost her appetite, and suffered from nausea; her strength gradually diminished, and she was soon confined to her bed. The mother called in the quack doctor, who encouraged her to persevere by telling her the fever was an effort of nature for the end proposed. She persevered, and in a few days lost an only and a lovely daughter. (We examined the medicine which had been exhibited, and it proved to be oil of savin.")

Having stated what fatal consequences may arise to the unprepared from the unexpected appearance of this function, as well as the sad results of an attempt to bring it on suddenly, I shall now proceed to make a few remarks on that mode of training girls which is best calculated to second nature in her cautious attempts to inaugurate this new and important function.

1. With respect to the body, there is no reason for interfering with habits and customs which have hitherto maintained girls in an average state of health. The regular performance of the various functions should continue to be insured, and the frame should be invigorated by an increased amount of out-door exercise. In dress there are two evils to be guarded against: insufficient and injudicious clothing. Rich young ladies suffer as much from insufficient clothing as the daughters of the destitute, for poverty and fashion are two tyrants which exact the same things, and often bring on the same diseases. In my work "On Diseases of Menstruation," I have laid great stress on the fact that girls are clothed in trousers until they are about to become women, and then trousers, drawers—all are thrown aside, and the body is exposed to our piercing easterly winds, and to the atmosphere, which in the morning and evening is at all seasons cold and clammy, or to cutting draughts when waiting for the carriage, in hall or passage, after continued active exercise in a hot crowded room. Should fashion command, the loins will be constantly kept in a state of undue warmth, by two or three inches of padding, petticoat, and dress; why then should the slenderest covering be denied to a part of the body hitherto carefully protected? If I dwell upon this subject, it is because my opinion differs from that of many practitioners: the late Mr. Pennington, for instance, though I know not for what reason, used to recommend a totally different plan from that which I advocate. In my opinion the use of drawers would preserve women from numberless infirmities, sometimes even from death. A great physician, Joseph Frank, relates that a beautiful girl, a relative of his, in splendid health, went to a ball, (although the period of the month was inconvenient to her) and returning home while still in perspiration, was seized with acute inflammation of the womb, and died of that complaint on the fourth day from the attack. I could detail several cases from my own experience in which a similar cause produced inflammation of the womb, of the ovaries, or interminable menstrual derangements, I therefore consider short drawers an indispensable article of female attire at all ages.

2. With regard to the government of the mental faculties, we have little to say, except that one ought not to be more fully developed than another; they ought to be kept in a regular state of counterpoise, so as fully to develop the reasoning powers, and by more completely occupying the time and thoughts, to keep in check the too sudden development of those sentiments which have already tried their young strength in many a way, and which, in girls of the higher classes, often assume a wrong direction, attain a morbid intensity, and are productive of the most deplorable consequences. Far better off in this respect are the daughters of the poor, in whom the wild freaks of imagination are successfully kept under by poverty and hard labour, which as effectually put an extinguisher on romance as they dull the acuteness of intellect, and give the skin a plebeian hardness.

3. The proper direction of the affections is one of the most sacred duties of a mother, and if we touch on a subject so delicate, it is because, in accordance with her destiny, her moral and mental conditions effectually react on the organs, directing that periodic flow which *critically* determines the measure of woman's health; for a mother, in attempting to perform her duty towards her daughter, to deny the validity of this principle in its highest earthly manifestations, would be folly: it should be admitted, directed, and judiciously developed by a mother's conversation and that of well-chosen associates. Novels and romances, in general, should be spurned, as capable of calling forth emotions of a morbid description, which, when habitually indulged, exert a disastrous influence on the nervous system, sufficiently explaining the great liability of women of the higher classes to hysteria and nervous diseases. It may be contended that many of these works contain excellent principles and admirable precepts of morality, but what do girls care about moral axioms, which are almost always obscured in the brilliancy of fiction; they seek for the stirring adventure, the extravagant romance, the victorious hero, as if there were not sufficient romance in real life to excite the young imagination without stimulating this faculty by fantastic creations, evoking heroes as gods of their idolatry, with whom in fancy they could live for ever in regions of boundless and unfading bliss.

4. How should girls at this critical period be treated? I answer by that happy mixture of firmness and mild-

ness oftener met with in the mother than in one of the sterner sex, who is too apt to check by parental severity those faults which he may himself have caused by undue indulgence. It is not wilful wickedness that afflicts girls at this important period, but a transient want of self-control, the consequence of a new influence obscuring for a time the clearness of the moral principle. Until nature asserts her sway, the adoption of gentle means, and a soothing treatment, to keep in check all eccentricities, added to the firm assertion of the rights of reason, blended, however, with the tenderness of a mother's affection, (without which all reasoning would be powerless,) seems to me the best plan to be pursued; for harsh treatment might, and probably would, give a permanent warp to the yet unformed character.

Thus have I attempted to show the medical and moral principles which should guide us in the management of women at this important crisis of life, and on some other occasion I shall offer a few reflections on the right management of women at the first appearance and during the persistence of menstruation.

Provincial Medical & Surgical Journal.

WEDNESDAY, MARCH 19, 1851.

"Uneasy lies the head that wears a crown," says the prince of English poets. Shakespere had not any experience in conducting a medical journal, or he would assuredly also have left behind him some testimony as to the occasional discomfort of that less dignified portion of the human frame which, metaphorically speaking, occupies the Editorial chair. Our position, at least, is no exception to the general rule of Editorial malaise. Having so lately been reprehended by one party for not taking sufficient notice of medical politics, and by another for taking too much, we had imagined that a respite would have been granted us, and that we might have been allowed to "pursue the even tenor of our way," if not with praise, at least without censure. *Sed Dis aliter visum est*, and we have once more to take up the cudgels in our own defence.

"A Frequent Reader," whose uncivil letter appears in our last number, finds fault with the publications of the Association. For this we should not have blamed him, did we see just cause for his animadversions; for, every man has a right to his opinion, and having the honour to be placed in a prominent position, we are content to pay the penalties, as well as to receive the gratification contingent thereupon. But without presuming to think too highly of ourselves, we must beg leave to suggest that "A Frequent Reader" reads oftener than he reflects, or he would not have penned the epistle in question. In the first place, if he be at the pains of inspecting this journal he will find that the "varied type," which he seems to regard as a desideratum, is really made use of; though upon what grounds, beyond that of typographical convenience, this should be regarded as a desideratum, we do not see. Again, before he is so hard upon the foreign department, it would be well that he exerciseth himself a little upon foreign medical literature; a personal acquaintance with the task would, we predict, tend considerably to mollify his critical asperity.

We may safely appeal to the experience of our brother Editors for confirmation, when we assert that it is no easy thing to keep up a constant supply of valuable foreign medical information. The Italian journals are next to worthless as far as original matter is concerned, all their best articles being mere transcripts and that chiefly of British writings. The French and German journals are not, we admit, open to the same remark; but in these also, the amount of really available matter is comparatively small. It is true that in German literature there is much, in a purely scientific view, of great interest; but we would ask, if, in a journal mainly devoted to the use of the busy general practitioner, we should be thanked for elaborate disquisitions on the more abstruse subjects connected with our profession? It is a matter of anxious consideration with us to make our journal one of practical utility, and our foreign selections are, whenever we have the material, made with that view. It has appeared to us that by giving a concise abstract of the proceedings of the foreign scientific societies, together with the translation of such articles in the French and German journals at our disposal, as have a direct clinical bearing, we best fulfil the important trust which has been confided to us, as a portion of our duties; but we shall ever feel obliged for any hints, by the adoption of which our usefulness to the Association can be enhanced; and if our "Frequent Reader" will favour us with a more definite idea of the means by which, in his opinion, our labours may be rendered more worthy, we shall have much pleasure in tendering him our acknowledgements; and the more readily if his suggestions be made in his own proper name.

The daily papers contain another proof how little sympathy exists on the part of the public towards the medical profession, and how ready they are to support any charlatanry, however absurd, to its detriment. It seems that a Lieutenant Ackerly, whose bedlamite advertisements occasionally appear in the newspapers, has precipitated the death of an unfortunate man, who had been burnt in a colliery explosion, by asphyxiating him with the fumes of a wax-candle put under his nose, which is his way of contesting with homœopathy and other quackeries the honour of curing cases in which the "regular faculty have failed." Instead, however, of re-animating the breath of life, which his noteable invention was to have done, he very speedily extinguished it, and was accordingly put on trial for manslaughter. The result, as might have been predicted, was his acquittal, the notice of which was received with cheers by the enlightened audience.

Reviews.

Operative Surgery. By F. C. Skey, F.R.S. London: John Churchill, 1850. 8vo, pp. 709.

In his preface to the above treatise on operative surgery, Mr. Skey informs us "that he does not profess to give the multudinous opinions of other men, although he has not entirely withheld them," alleging as a reason "that the character of his mind is not attuned to authority, and that it has been his practice as well as his principle, to think for himself." We must therefore consider the above work not as a complete treatise on the operative department of surgery, but rather as a collection of the peculiar views held by Mr. Skey, in relation to the various operations performed upon the human subject.

The first two chapters are taken up with introductory remarks, which are in the main exceedingly applicable, conveying in clear and concise terms the duties of the operator and of his assistants, and explaining the ordinary laws of medical ethics as far as they relate to the operative surgeon in consultation. We believe in these chapters there is only one instance in which Mr. Skey adopts any plan differing from that usually practised, and that exception relates to the mode and time of the first dressing after important operations, which he advises should be commenced at the expiration of forty-eight hours, or even as early as thirty-six hours afterwards. This is certainly much earlier than is generally recommended, nor do we believe it possible to remove all the adhesive plaster from the line of incision at so early a period, without disturbing the recently-formed adhesions. Mr. Skey objects to the use of the isinglass plaster, which he thinks positively injurious. In this opinion we cannot agree, as we have never seen the adhesive process so perfectly carried out as by the adoption of the plan recommended by Mr. Liston, one of the most important features of which consists in the rejection of all irritating plasters, the line of incision being simply covered with the above plaster. The isinglass also allows, by its transparency, of the situation of the sutures being detected by the eye, and removed at an early period without the necessity for displacing the dressings.

The third, fourth, and fifth chapters comprise the subjects of Dislocations, Bandages, and Fractures, in which there are some useful suggestions, though on the whole the directions are somewhat meagre. For instance, under the head of bandages, four kinds only are enumerated, and again under the head of fracture of the thigh, we seek in vain for any directions for the application of the various apparatus which have been devised for this troublesome accident. A short allusion to Liston's splint and a still shorter to a plan proposed by our author, is all that we find on this controverted point.

Under the head of Aneurism, (which, together with the kindred subjects of Wounded Arteries and Nœvi, form the matter of the sixth chapter,) we have a needle described, which was invented by the late Mr. Alcock, and which, in Mr. Skey's opinion, is far superior to those generally employed. We can speak ourselves as to its efficiency, having shown it originally, twenty years ago, to Ferguson, the instrument-maker to St. Bartholomew's Hospital, soon after its invention by Mr. Alcock, and we have often been surprised at its value having escaped the notice of many of our hospital surgeons. We strongly recommend our readers to procure it, and try it in almost all cases where an artery requires a ligature to be carried round it, whether in a superficial situation, or at the bottom of a deep cavity.

In the above Chapter we naturally expected to find some allusion to the cure of aneurism

by compression with the spring apparatus, especially as Mr. Skey professes to avoid most scrupulously all appeal to the knife when practicable, we were therefore disappointed at finding only a short allusion to the plan of pressure *with the tourniquet*, without any reference to the numerous successful cases in Ireland and elsewhere, which have been recorded as treated with the elastic apparatus.

We pass over the following heads, viz., Venæsection, Arteriotomy, and Varicose Veins, as requiring no remarks, the description being, though short, practical, and useful to the young surgeon. The next division is that of Amputations, in which Mr. Skey enters into the question of the relative advantages of the circular and flap operations. Here we find many observations of great value, as coming from a surgeon who has tested the two modes, both in his own practice and in that of his colleagues. Mr. Skey seems inclined to abandon the flap operation, from the fact that the stump, though more sightly, is not so useful as that following the circular operation. Under this head also Mr. Skey introduces a tourniquet, invented by himself, which he thinks superior to the Italian instrument now so commonly employed; but Mr. Skey's tourniquet is not applicable high up in the thigh, or in the groin, which is a serious objection to its use, and is a chief advantage in the ordinary *presse artére*. The particular amputations are given in the usual manner, without any novelty, though with sundry omissions, but, as we before stated, Mr. Skey only professes to give the results of his own practice, and is not, therefore, open to criticism on this point.

In discussing the subject of Hernia, Mr. Skey advocates the propriety of opening the sac in almost all cases, adducing several cogent reasons for his opinion, which we have not room to enumerate, but leaving the question to be decided by the unerring test of statistical inquiry.

The thirteenth Chapter comprehends the operations of Lithotomy and Lithotrity, with a short comparison of their respective merits; the latter of these is dismissed with a very meagre description of the various instruments, and the mode of using them, whilst the former has received the utmost attention from Mr. Skey, indeed this is evidently his pet subject, and he has succeeded in doing it full justice. Much information may be derived, even by the practised surgeon, from Mr. Skey's description of the operation, which is characteristically graphic in its nature. The chief peculiarities in the method advocated by our author, consist in the adoption of a staff, with a large and peculiar curve, and in *his carrying his first incision at once into the groove of the staff*, careless alike of the bulb and its artery, and risking much injury, we think, by an attempt to expedite the operation, and to display unusual dexterity. We should scarcely recommend our readers to imitate the feat, though we have reason to believe that Mr. Skey usually succeeds in his attempt.

We have thus passed in review the principal subjects upon which Mr. Skey has offered his opinions, with the exception of his chapters relating to the operations on the eye, which are so short and carelessly written, as to be unworthy of notice. It will be perceived that we have discovered little to admire in these opinions, though where we have been able to do so, as in the remarks on amputations and lithotomy, we have gladly availed ourselves of the opportunity. As containing the results of Mr. Skey's experience, we can only regret that, with the opportunities which he has enjoyed, "his mind has been so little attuned to authority" as to prevent the comparison of his own experience with that of others, in the numerous instances in which it would perhaps have been of service to himself as well as to his pupils and readers. As a treatise on operative surgery, his work will not bear the test of careful examination, but as recording the experience of a metropolitan surgeon, it would be idle to say that some good may not be gleaned from its pages.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

NOVEMBER 7TH, 1850.

MR. WICKENDEN IN THE CHAIR.

Deposit of Cancerous Matter in the Liver to an unusual Extent; slightly in the Lungs and in the Kidneys.—By Dr. RUSSELL.

THE liver was enormously enlarged, the proper tissue being almost entirely replaced by cancerous matter in nodules more or less coalescing, which, however, had not formed any projections at the surface. It weighed ten pounds. A like deposit was just commencing in the kidneys, and had formed several nodules in the lungs. The abdominal glands were healthy.

By the Microscope.—The deposit was found to be composed of cells, mostly spherical, with bright nuclei, the largest 1-1667th of an inch, the majority were much smaller. There were one or two compound cells; very few of the dark granule cells, and very little fat. The stroma was very scanty; it formed a delicate sheet. The hepatic cells were free from fat.

The patient was a pearl-button maker, aged 38. He had only remarked the tumour four months before death, though he had pain in the kidneys and at the right side for two years. He was confined to bed only for the last six weeks, with incessant vomiting and severe lumbar and abdominal pains. Towards the last his urine contained abundance of lithic lozenges. Emaciation only proceeded rapidly during the last three weeks, and he had not the aspect of malignant disease previously. He had never jaundice or anasarca.

Cancerous Degeneration of the Lymphatic Glands of the Neck and of the Loins, involving the Pancreas.—By Dr. Russell.

The glands of the right side of the neck formed a mass of stony hardness, lying on the transverse processes of the vertebræ, and extending into the thorax to the aortic arch, where it covered the origin of the innominata and reached to the root of the right lung; the right subclavian and common carotid artery, and a portion of the left vena innominata, were embedded in it. A second mass lay behind the pancreas, and having become identified with it, was converting it into its own tissue. The duodenum and pylorus were thrown forwards, but were uninjured. The abdominal tumour enveloped the branches of the aorta, and sent a process along that vessel, closely connected with the middle coat, to the bifurcation. A small detached tumour also adhered to the thoracic aorta. The mesenteric and bronchial glands were healthy. The lungs healthy. The heart presented a very remarkable appearance; it seemed to have lost substance; its vessels being very prominent, tortuous, and thin, and its serous membrane very loose; the surface was opaque. The pericardium contained half a pint of fluid blood; its source could not be discovered. There was plentiful deposit of atheroma in the aorta. The lower twelve inches of the colon presented a remarkable and abrupt double turn, maintained by old adhesions.

Microscopic examination.—Milky fluid flowed abundantly from the pancreatic tumour, which had the character of soft scirrhus; rather more sparingly from the cervical tumour, which was very hard and crisp. Neither tumour presented the fibrous bands usual in scirrhus. The fluid contained a multitude of fine cells. Varieties of the caudate and fusiform prevailed, some of which reached the 1-125th of an inch in length. A large number of the cells approached the spherical shape; they were from 1-1429th of an inch downwards. There were a few large compound cells, and many large granule cells. All the cells contained large nuclei. The stroma formed merely thin delicate sheets, loosely crossed in various directions (in the cervical tumour *only*) by beautiful bands of well-formed white fibrous tissue; it became quite transparent by acetic acid, nuclei only being left.

The patient was a smith, aged 64. There were few characteristic symptoms. Slowly progressing emaciation, and gradually failing strength for six or seven months, and unmanageable constipation. The cervical tumour had been noticed "several months." He had never a decided aspect of malignant disease.

Fatty Degeneration of the Muscular Fibre of the Heart: the Cavities of the Heart were generally Dilated.—By Dr. Russell.

The valves were healthy; the auricular orifices large; there was a copious deposit of fat upon the right ventricle externally, especially towards the apex, but none upon the left side of the heart. The muscular fibres of the lower half of the right ventricular wall were gradually supplanted from without inwards, by a fat-like substance, increasing in thickness towards the apex, where only a thin muscular layer remained; the heart was generally very flabby, its muscle of a uniform deep colour; the aorta contained atheroma very sparingly, but it had quite degenerated the middle coat, where it had existed. The other organs were congested. There was a large amount of fat under the skin, upon the pericardium, in the peritoneal processes, and around the kidneys. The veins were full of dark blood.

Microscopic examination.—The *degenerated muscle* of the heart was composed of fat in large vesicles, and areolæ, and among it small patches of the remains of the muscular fibre, of which the ultimate fasciculi were well formed, but the striæ were scarcely visible. *Near the degenerated portion*, groups of fat vesicles lay among the muscular fibres; the fasciculi were delicately mottled, and without striæ. Of the rest of the heart the fasciculi were filled with minute bright granules, in longitudinal rows, and with imperfect indication of striæ. The liver and kidney-cells were free from fat.

The patient was a carrier, aged 61. He had ailed for 14 years. There was evidence of diseased heart for eight years. The last six months he suffered from short breath, independently of exertion, which often amounted to distressing orthopnœa, and from incapacity for exertion. He had a distressed haggard countenance, though free from blueness. His pulse was very irregular, about 80. The sounds of the heart were obscure, as in hypertrophy; the impulse feeble, as in dilatation. He had cold feet only for the last six weeks, and anasarca for the last three weeks; but it rapidly became extreme. There was sometimes some cerebral excitement, and he had had symptoms of congestion of the brain more than once. His death was quite gradual.

An Atrophied Placenta containing Apoplectic Clots after Abortion.—By Mr. Bindley.

It was irregularly lobulated. One of the lobes contained a large coagulum, another portion was doughy and contained blood extravasated into its vascular network, which was degenerated into a pulpy mass; the whole organ was atrophied; the funis thin; the vessels pervious. The patient was a young woman, quite

healthy, and had previously never aborted. She had five children. She aborted at the seventh month, after a slight injury to the abdomen six weeks before.

Fluid taken from a patient with Ovarian Dropsy.—By Dr. Russell.

The fluid was opaque, and of a very dirty colour, strongly albuminous, specific gravity 1018, neutral. By the microscope, it contained a small number of imperfect cells, from 1-715 to 1-2500th of an inch in diameter, and plates of cholesterine. The patient was a lady, aged 62; she had six children, was of quite a healthy appearance, her catamenia ceased naturally twelve years ago. The fluid had been forming ten months; fourteen quarts were removed from one cyst; but another remained. She died soon after, under what circumstances was not known, but she had quite recovered from the effects of the operation.

Tumour enclosing a Calcareous Concretion, involving the Right Optic Thalamus.—By Mr. Bindley.

The place of the right optic thalamus was occupied by a tumour, the size of a walnut, encased in a thin lamina of healthy nervous substance, apparently the remains of the thalamus. It projected considerably into the ventricle, and enclosed a calcareous concretion the size of a filbert, of irregular figure. The tissue of the tumour was distinguished from nervous substance by its greater consistence, and its yellowish pellucid colour. The fresh section had a striated and gelatinous appearance; small earthy particles were disseminated throughout its substance. The tumour and its enveloping brain-substance became quite detached by maceration in spirit. The ventricles were dilated by limpid serum, and three ounces of limpid serum lay in the subarachnoid space. The veins and sinuses contained less blood than natural. The other organs were healthy. The uterus was gravid.

By the Microscope.—The tumour seemed to consist of small cells and granular matter, with a sparing intermixture of fibrous element.

The patient was a servant. She was a young woman, and unmarried. She died quite suddenly after a short struggle, having only complained of some confused pain in her head the day before. She had not exhibited any marked symptoms of cerebral disease.

Large Aneurism of the Ascending Aorta, nearly obliterating the Innominata.—By Dr. Fletcher.

The aneurism was of the size of a large orange; it sprang from the first band in front of the origin of the innominata, and projected upwards and to the right, compressing the bronchus. It was quite filled with firm laminated fibrin, and completely plugged the origin of the innominata, but left the aorta free. The ascending portion of the aorta was somewhat dilated, and had in its front three small pouches in a vertical line, formed by the healthy outer and inner coat, the middle being greatly thinned. The aneurism had protruded through the upper bone and part of the middle bone of the sternum, the intervening cartilage being left; very hard fibrin lay between the remaining bone and the periosteum. The heart was healthy. There were a few tubercles in the apex of the lungs.

The patient was a sawyer, aged 40. He was accustomed to make great exertions, and was extremely dissipated. He spat blood first about two years and a half since, after a violent strain; it was followed by stitches in the right side, and then by some palpitation. Six months after a prominence appeared at the top of the sternum, and simultaneously some dysphagia with solid food, and dyspnœa. He soon became unable to work. His voice became changed, speech being often very difficult if pulsation were excited in the tumour. A hard cough troubled him, and he was much emaciated and enfeebled a year before death. At that time the upper bone of the sternum had been ulcerated through. There was no bellows sound in the tumour. The arteries from the innominata did not pulsate, though there was no deficiency of heat nor of power in the parts they supplied. By treatment his symptoms were much reduced, and his health improved, but he subsequently fell off again, and died gradually of exhaustion.

Extensive Tubercular Deposit, with very Local Degeneration of the Aorta.—By Dr. Fletcher.

Both lungs were filled with tubercular deposit in all the stages, and the tissue was generally condensed, particularly at the apices, where was a single large cavity; scattered ulcers were in the jejunum, to within two feet of the duodenum, and more thickly placed in the ilium, with external deposit of lymph; the mucous membrane, for ten inches of the ascending colon, was quite destroyed with the thickening of the coats; there were ulcers through the rest of the colon; the mesenteric glands were healthy; the liver was mottled with yellow, and unctuous; the ascending aorta was greatly dilated at its commencement, and presented a rim, two inches in breadth, of osteo-cartilaginous structure, studded with bony spiculæ; the heart and rest of the artery were healthy.

The patient was a carman, aged 35. He was in perfect health till he received an injury to his chest four years and a half since, causing an illness. He was much exposed by his trade, and drank freely. A year and a half ago he was found to have general condensation of the right lung, and local pleuritic effusion in the upper part. It was relieved, but subsequently the symptoms of advanced phthisis were presented, with severe diarrhœa and hoarseness.

Gun-Shot Wound of the Thigh.—By Mr. Pemberton.

The neck of the femur was fractured, partly within and partly without the capsule. Shot and fragments of bone lay in the wound. An old fracture, united, existed in the lower third of the femur. The patient was a labourer, aged 50, intemperate. He received the injury after drinking, in a quarrel. The charge entered from within, about six inches below the pubes, and passed out behind the trochanter. He died on the

eighth day, having had rigors during the last four days, with great prostration. The diagnosis was confused by shortening of the old fracture.

DECEMBER 5TH, 1850.

MR. PARTRIDGE IN THE CHAIR.

Heart enormously Hypertrophied by Contraction of the Aortic Orifice.—By Dr. FLETCHER.

The heart weighed one pound and a half; the capacity of the left ventricle and the thickness of its walls were doubled; the left ventricle formed the apex of the heart and extended quite behind the right ventricle. The aortic orifice was contracted to one-third its usual capacity, by thickening and corrugation of the valves; the other valves were healthy. The right walls were thick. There was half an ounce of bloody fluid in the pericardium. The lower lobes of the lungs were congested and friable; there was general adhesion of the right pleura, and scanty bloody fluid in the left. The liver was of a buff colour; acini confused. The patient was a lawyer, aged 29. He had rheumatism severely ten years ago. His last illness was of six weeks' duration. It commenced after exposure to cold, followed by rheumatism, and then by pain and dyspnœa, and other very urgent symptoms, becoming speedily fatal.

Fatty Degeneration of the Heart.—By Mr. BINDLEY.

The lower-third of the anterior wall of the left ventricle is mottled, much thinned, tears readily, and presents the characters of fatty atrophy; there were also some spots of degeneration in the columns of the right ventricle, whose walls are thin; the ventricles are dilated. The right coronary artery is contracted by osseous deposit; there is a large deposit of fat on the base of the heart and along the coronaries. The arch of the aorta is dilated and atheromatous. The laryngeal and pulmonary mucous membrane is dark coloured; the pulmonary veins are plugged with dark coagula, most so in the middle lobe of the right lung, where there is much œdema. The kidneys are in an early stage of granular degeneration; there is a large deposit of fat under the skin, on the pericardium and in the abdomen.

By the Microscope.—The degenerated tissue, was without striæ or nuclei; in place of them, molecules and minute globules of fat; elsewhere the tissue was healthy.

The patient was an engineer, aged 61, very corpulent for the last two years. He had an apoplectic attack eight years since, and again two years ago, and became unable to take exercise. He was subject to constipation, vertigo, occasional slight gout, bronchitis, neuralgia of the scalp, erythema of the ankles, and constriction of the abdomen. The last month he had constant attacks of angina, with great dyspnœa at night; œdema came on; his urine became very albuminous and with lithates; anasarca affected the face and upper extremities; orthopnœa, blueness, and low delirium. Death by asphyxia in a paroxysm.

Perforating Ulcer of the Stomach, with surrounding Disease.—By Dr. FLETCHER.

The ulcer was of the size of a fourpenny piece, in the anterior wall of the stomach, and close to the lesser curvature. The neighbouring glands were enlarged, dead white, and partially broken down. The small omentum was greatly indurated, involving the vena portæ. The abdomen contained lymph and fluid. The patient was a blacksmith, aged 56. Ascites came on gradually through several months; he suffered much from constipation, anasarca came on, and much pain in the abdomen. His urine was scanty. He died in a few hours, having vomited and been seized with severe pain.

Large Osseous Tumour of Femur; fatal by undergoing Malignant Degeneration.—By Mr. PEMBERTON.

The tumour occupied the inside of the lower-third of the thigh; it was of conical shape, and nearly as large as an adult head, it sprang from the lower-third of the shaft of the femur and from the inner condyle, completely avoiding, however, the articular face, and lying entirely on the inside of the limb. Its transverse diameter from the outer condyle was nine inches. It was formed of bone, of close ivory texture and white colour. The cancelli of the portion of the shaft remained distinct, but partly replaced by lymph. At the lower part the shaft gradually merged into the tissue of the tumour. The lower-half of the tumour was excavated by ulceration into a large basin, eight inches in diameter, having a foul sloughy surface. On the posterior face of the tumour was a fibrous growth, composed of cells, not unlike the spongy vascular tumours of bones, which by the microscope manifested a fibrous stroma, with numerous small globular, caudate, and fusiform cells. The knee joint was natural; patella pushed upwards.

The patient was a female, aged 45. She had ten children. The tumour commenced during pregnancy, seven years ago, and grew slowly. During the last sixteen months her health failed, and the growth was more rapid. Ulceration commenced three months before death; at the commencement only it was attended by hæmorrhage; it was very rapid in its progress. In this period the vascular tumour formed. The state of the inguinal glands, when seen by Mr. Pemberton, prevented amputation. She had no inherited malignant taint.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

TUESDAY, FEB. 11, 1851.—DR. ADDISON, PRESIDENT.

*Case of Cæsarian Section.**—By H. OLDHAM, M.D.

[The following is the concluding portion of the discussion on Dr. Oldham's "Case of Cæsarian Section," which from its great length we were compelled to omit in our last number:—]

Mr. WREN said that the observations he had to make would be short, as much as he had intended

* Concluded from page 154.

to have said had been spoken by Dr. Murphy. Whether Dr. R. Lee's remarks were to be regarded as personal or not, he could not help feeling that the observations made by that gentleman affected him (Mr. Wren) seriously, and more particularly as they had been reported in the medical journals. The charge against him amounted to this—that had the patient whose case was before the Society, fallen under the care of Dr. West at any early period of her pregnancy, Dr. Lee believed that the result would have been different. He (Mr. Wren) contended that this assertion was most unwarrantable and unjust. He would beg to ask Dr. Lee whether it was usual for a practitioner to examine his pregnant patient (with the structure of whose pelvis he was ignorant) without a sufficient cause and excuse for so doing. Would permission to do so be granted? He (Mr. Wren) believed that it would not, unless some just and reasonable cause presented itself. Now the symptoms presented in the case under discussion were not such as justified the proposition of such examination, or could lead to the suspicion that disease existed. Dr. Lee had depicted the symptoms in a manner which might lead the fellows of the Society to infer that the patient suffered vastly more acutely than she really did. But he (Mr. Wren) would now trouble the Society with his own version of the symptoms at the time he first saw her, and afterwards, up to the day of the operation, and those marked by inverted commas were the identical words copied and sent to Dr. West. The notes were short, and chiefly from recollection, but they were most strictly and conscientiously correct. "She represented her health as having been always delicate; complained of distressing heartburn, pain in the head and throat, sickness, loss of appetite; stated that she had constant fainting fits—that a morning rarely passed without such. Pulse 130 and upwards; bowels irregular and constipated; dreaded her confinement, and observed that she was sure she could not go through it unless she was rendered insensible by means of chloroform, the effect of which she had experienced. —Jan. 4th. She told me this day, that on the occasion of my previous visit she was nervous and agitated; had had several fainting fits; these usually occurred in the morning, on first awakening; heartburn not relieved. Under the treatment pursued, with little or no variation for nearly three months, she regained her appetite, the sickness subsided, the fainting fits became rare, indeed, almost ceased, and she had much more rest at night; her pulse, however, still remained at 120.—March. At the commencement of this month she complained of suffering severely from cramp, and that the slightest exercise produced it, and pleaded this as an excuse for not taking the exercise which I urged. Upon each occasion of my requesting her to allow me to examine her heart, she objected, stating that the medical men who had previously attended her, amongst whom was Dr. Hamilton Roe, had always pronounced the heart to be free from disease; at the same time she remarked, unsolicited by me, that they had all told her her pulse was never less than 120." Now he (Mr. Wren) would ask if there was one symptom that could lead to the suspicion that pelvic disease was present? Were not the symptoms, in fact, such as would or might present themselves in an ordinary case of pregnancy? With regard to the statement of Dr. West, in the paper, that this patient was incapable of walking, he begged to say this was an error—a mistake into which Dr. West might have fallen from misunderstanding her husband; at all events it was not correct. The husband, in fact, positively affirmed that his wife went daily, and without the least assistance, from the sitting-room, on the first floor, to the water-closet, down three flights of stairs, and across a yard, twenty feet in length. For the last two months of her life, the husband was in the habit of carrying her from her bed to the sofa and it might be inferred from this that she could not walk, but this would be a mistake. Invariably, when he (Mr. Wren) called to see her, she rose from the sofa, and on his leaving the room, walked to the door, and exhibited no sign of lameness or any awkwardness that could lead to the suspicion of the existence of pelvic deformity. It might be inferred from the remarks made by Dr. Lee, that he (Mr. Wren) had frequently seen her in bed; but this he had never done; and she had always found some excuse to prevent him from examining the heart, and remaining in bed. She was a very sensitive person, not giving information about herself readily, and her husband had never made a remark which would lead to the suspicion of any malformation. There was not, as Dr. Lee had stated, violent pain in the chest, extending down the back and loins, nor any symptom whatever of pelvic disease. He had expressed himself perhaps imperfectly, but he trusted that he had said sufficient to justify himself against the charge which had been made against him. (Cheers.)

Dr. West now rose, for the purpose of making some remarks; but it being observed by the President that the usual time for adjournment had nearly arrived, and as many fellows were anxious to address the Society, a motion was made, seconded, and unanimously carried, that the discussion be prolonged for half or three-quarters of an hour longer, according to the discretion of the President. Hereupon

Dr. Ashwell remarked, that it was easy to understand how men enthusiastically devoted to the pursuits of a profession should occasionally express themselves with an appearance of something like personality, when in fact, after the excitment of the discussion was over, nothing of the kind was really intended. Still it must not be forgotten, that by energetic collisions of this nature, truth was elicited; and, said Dr. Ashwell, "I doubt not the members of the Society who have entered most warmly into the question now before it would, with great pleasure and most impartially, accord to Dr. Lee his full measure of praise, if ever he shall again announce and establish other discoveries as illustrious as his demonstration of the uterine nerves. But, Sir, the question now in debate is a most important one, being no less than the determination of the worth and desirableness of the Cæsarian section. Although agreeing in a great deal that Dr. Murphy had said, he still thought the operation was most undesirable, and, like all the operations of abdominal obstetric surgery, all but uniformly fatal. In reference to the case brought forward by his friend Dr. Oldham, he did wish that he had persevered for a *longer* period in his attempts to deliver by embryotomy, before resorting to the Cæsarian section. Still, in saying this, he was quite aware that

he might be met by the infelicitous result of his own case which had been quoted by Dr. Oldham, and in the management of which he had enjoyed all the facilities and appliances which Guy's Hospital so richly afforded. It is true that he (Dr. Ashwell) intimated, in that case, if he had seen the patient earlier, the Cæsarian section might have been properly resorted to, although it ought to be stated, that, in juxta position with that remark, he had emphatically said that premature labour, artificially induced, was the appropriate measure in such cases. Still he was quite aware how difficult, and in some instances, how insuperably difficult was either craniotomy or the breaking up of the child. This fact (said Dr. Ashwell) ought not to be concealed; for no one except he has himself had the management of such formidable cases, can form an adequate idea of the obstacles to be overcome. But even with this admission, he (Dr. Ashwell) still said, that in almost every instance this dreadful operation should be negatived. The cases adduced show how few, how very few, recovered; this brought him to the conclusion that premature labour, and where this had been neglected, craniotimy and the dismemberment of the child, with all their difficulty and delay, were far preferable to delivery by the Cæsarian section. Certainly, in those unhappy cases where there was a suspicion that the pelvis was deformed, whether from mollities, or independently of this destructive malady, it was the great duty of the accoucheur to examine as early and as accurately as possible—that the membranes might be punctured, and labour induced at as early a period as the degree of deformity rendered necessary.

Dr. Tyler Smith thought it should in all fairness have occurred to Dr. Murphy, that by far the greater number of the craniotomy operations of Dr. Lee were performed upon cases of other medical practitioners, to which Dr. Lee had been called at the last extremity, and, in which, therefore, no question respecting the induction of premature labour could have been entertained by him. With respect to the Cupar case it must be considered as one in which nature wisely performed the operation of premature labour, and destroyed the fœtus by rendering the placenta unfit for its support. In the case detailed by Dr. Oldham, it appeared to him a matter of regret that the child was not destroyed at the earliest possible moment after the commencement of labour, or that time was not permitted to elapse after craniotomy, so as to allow putrefaction and softening to proceed before the efforts at extraction were made. In Dr. West's case it was also to be regretted that the attempt to perform craniotomy was not made, particularly as it appeared that Dr. Ramsbotham had leant to this plan in the first instance. In cases of osseous deposit, it was difficult to estimate the amount and density of the bony matter contained in the pelvis. In some cases on record the bony structure had broken down, so as to allow of delivery, and many cases which seem at first to present insuperable difficulties become less formidable when craniotomy is attempted. In most cases it was impossible to say without a trial that craniotomy and extraction might not be performed. It was also unfortunate that no reference had been made in Dr. West's paper, to the induction of premature delivery, and no regret expressed at the time for the performance of this operation had passed without the detection of the pelvic deformity. If that regret had been expressed, the operation for the induction of abortion or premature labour and the Cæsarian section, could not have been brought before the Society in such violent collision. He (Dr. Tyler Smith) had understood Dr. West to say, in the few words he had spoken at the close of the last meeting, that the induction of premature labour so ably handled by Dr. Lee, was fully recognised by the teachers of midwifery in this country. He begged to differ from that opinion. Dr. Lee had referred to the induction of premature labour and also to the induction of abortion in the early months in cases of high distortion—an operation which of necessity sacrificed the ovum to preserve the life of the mother. Dr. Wests's observations could only refer to the induction of premature labour at a time when the child was viable. He contended, however, that neither premature labour nor premature abortion were held in sufficient consideration by some obstetric teachers, though the operations belonged to this country. Dr. West had himself recently published an elaborate historical essay on the fluctuations of opinion which had existed respecting the merits of turning, and the use of the forceps, in cases of distorted pelvis. Now, it was remarkable, that throughout this essay, no reference whatever was made to the induction of premature labour, a more important matter in such cases than either turning or the forceps, which came between them, and without which it was absolutely impossible to estimate their respective merits. Dr. Rigby, also, whose name has been mentioned in connection with one of the cases of Cæsarian section brought prominently before the society, had written in his "System of Midwifery," a special chapter on the induction of premature labour, but he had not said one word about the induction of abortion in cases of high pelvic distortion. Dr. Murphy, in his published work "On Difficult Parturition," had only noticed the induction of premature labour in a cursory manner, and as a mode of saving the life of the child. Yet it was, without doubt, one of the most important points in the entire range of obstetrics. Dr. Lee had operated on one patient twelve times, and both the mother and several children were now living. In other cases the ovum had been destroyed many times in succession, in order to rescue the life of the mother. Some obstetricians entertained doubts of inducing abortion repeatedly in the same individual. Denman, who thought the fœtus suffered pain, originated this doubt, but it had not been developed until there were some teachers of midwifery in this country, who declared the operation should be performed once only, but that afterwards the wretched woman should be left to take the fearful chances of the Cæsarian section. To say this, was to assume the position of the Supreme Judge. As well might we refuse to cure syphilis the second time. Such a dogma was most monstrous. It was both absurd and immoral, under any circumstances, to prefer the life of an ovum, of four or five months, depending from day to day for its existence upon the state of the mother, to the life of a mature woman; and he trusted that one result of the present discussion would be to bring the subject of induction of abortion, as opposed to the Cæsarian section, into more prominent notice. Dr. West had said, that

in similar cases to the one he had related he would repeat the Cæsarian section, but he hoped that before the publication of his paper in the *Transactions* of the Society, some reference would at least be added to the all-important relations of the induction of premature labour and abortion in such cases.

Mr. SKEY apologized for rising to speak upon an obstetric subject; but as he was more or less implicated in two of the interesting cases which had been brought before the Society, he could not help rising and protesting most emphatically against the imputation which had been thrown against the practitioners connected with those cases of want of judgment and of rash practice. With regard to the case of the woman described in Dr. West's paper, Dr. West was himself responsible. When he (Mr. Skey) was called upon to operate, he did not go blindfolded to the proceeding; the operation was considered by all the obstetric physicians present, by Dr. West, Dr. Murphy, Dr. Ramsbotham, and Mr. Wren, to be indispensable. So much for his (Mr. Skey's) connection with that case; further remarks upon it he would leave to others. As to the former case, with which his name was associated, Dr. West and Dr. Murphy would seem to imply that that case was under the care of Dr. Rigby. It was not so; he (Mr. Skey), and he alone, was responsible for that case. The woman had come under his care in the hospital close upon the seventh month of pregnancy. What did he do? Was he to take the management of an obstetric case? He knew nothing of obstetricy. (Laughter.) No; but what did he do? Why, he called in consultation almost every obstetric practitioner of eminence; but he had not the advantage of the opinion of his friend Dr. Lee there. (Mr. Skey pointed to Dr. Lee who sat near him. Dr. Lee bowed.) But he had the advantage of the opinion of Dr. Rigby, Dr. Protheroe Smith, Dr. Fergusson, Dr. Locock, and also of twenty eminent physicians. He begged the physicians' pardon; he meant general practitioners. (Laughter.) He did not recollect their names; indeed they were "legion," but they were men well able to give an opinion on a practical question regarding this part of their profession. And what was the result? A corresponding statement of opinion of every one. Yes, every one declared that it was too late a period then to attempt to induce premature labour. Yes, he could have twenty names appended to the memorial that it was too late for such interference. Then came this question to him: Should he perform the Cæsarian section prior to the ordinary period of full pregnancy? His own opinion was that he should; but here the physicians stept in again, and said, No! This was the opinion of Dr. Locock, and also of Dr. Rigby, and the argument they employed was this:—the natural period was the most desirable, and to anticipate a natural process would be dangerous. Well, then, he determined to wait until the ninth month. He took the responsibility of the case fully, but he shared it with too good men, who were cognizant of all the circumstances, to fear that he had not been justified in what he did do. But after all, he was merely a creature in the hands of the obstetric physicians. He had nothing more to say; but he would direct the attention of this meeting to the pelvis of this woman. Here was the monster (taking it up). There, look at that (exhibiting it). Was there ever such a diameter? One inch and one-eighth in a dry pelvis. What would his friend there have done (pointing to Dr. Lee, who got got up to examine the pelvis). Would he have tried to deliver in this case, on a pelvis with a diameter of an inch and an eighth? He had never heard of anything like it. He did not believe that it could be done. He had spoken out upon the subject, as he felt bound to do. No one had a higher opinion of Dr. Lee than he had, and he had given him the first testimonial with respect to one of his discoveries. He mentioned that to show that he respected him. He would not dwell upon the subject farther, except to say, that when a question of difficulty arose, and a single mind differed in opinion with the large majority, he did think it became that individual to deliver his opinions with some degree of qualification and hesitation, and not to launch forth condemnation against those to whom he was opposed. (Hear, hear.)

Dr. LEE, who had been absent during the greater part of the evening by unavoidable professional business, having come into the Society a few minutes before, immediately rose after Mr. Skey had sat down, and took up the *monster* pelvis, which Mr. Skey desired might be handed to him. After rapidly examining all its dimensions, brim, cavity, and outlet, Dr. Lee expressed his utter astonishment that this pelvis could ever have been represented by Mr. Skey, and described as a highly distorted pelvis requiring the Cæsarian operation. Holding up the pelvis to the Society, Dr. Lee declared that the outlet was not distorted in the slightest degree; the tuberosities of the ischia could not be less than four inches and a half apart, and the point of the coccyx equally distant from the symphysis pubis. The whole hand might readily have been introduced into the cavity of this pelvis, to direct the perforator and guard the crotchet, had the operation of craniotomy been performed. Dr. Lee said the distance from the base of the sacrum to the symphysis pubis was certainly small, but in the sides of the brim there was sufficient space for the extraction of the head at the full period, and he had no doubt that in this case he could have safely accomplished the delivery with the crotchet, even at the time the Cæsarian operation was performed. Had premature labour been induced, even after this patient had been admitted into St. Bartholomew's Hospital, the delivery might have been effected with the perforator and crotchet, with the greatest ease and safety. Had premature labour been induced when the pregnancy was first ascertained, the operation of craniotomy would have been a very simple and trifling affair. Mr. Skey has informed the Society, with great warmth, that he takes the whole responsibility of this case upon himself, and that he is wholly ignorant of midwifery—knows nothing whatever of obstetricy. The whole responsibility of the operation, he said, devolved upon him; he alone was responsible for all the results, and that he had considered it necessary to protect his character against the imputation which he (Dr. Lee) had cast upon it. Sir, (said Dr. Lee,) I have never considered Mr. Skey responsible for the fatal operation, and I have never cast any imputation whatever upon the character of Mr. Skey, as a surgeon; I have been

told that he performed the operation admirably well. Mr. Skey said he took the whole responsibility of the operation upon himself, though entirely ignorant of midwifery, but he had no sooner said this than he shifted the responsibility to other shoulders, to a great many accoucheurs whom he named. I was not one of the number. The question before us is, not the responsibility or irresponsibility of Mr. Skey, who, as the Society must now perceive, is destitute of all knowledge of midwifery, but the point is, why the induction of premature labour was not had recourse to when the pregnancy was ascertained beyond all doubt, on the 27th of October, when Mr. Jolin, with Mr. Skey, decided that the Cæsarian operation should be performed? On the 7th of October, 1846, it was positively known that pregnancy existed, and that there was great distortion. On the 27th October, Mr. Skey decided that the Cæsarian operation should be performed on the 5th of November. (I believe it was Guy Faux's day.) The woman was admitted into the hospital to be operated upon; she remained in St. Bartholomew's Hospital all the rest of the month of November, the whole month of December, and during January, till the 26th. If there is an mistake in these dates, let Mr. Skey now correct it, and let him inform the Society why the induction of premature labour was not had recourse to between the 27th of October, 1846, and the 25th of January, 1847? Let Mr. Skey answer this question in a satisfactory manner to the Society. (Dr. Lee here paused, but Mr. Skey gave no answer, made no reply.) I maintain, Sir, resumed Dr. Lee, that the operation was wholly unnecessary and unjustifiable. I have the pelvis of a woman, at St. George's Hospital, far more distorted, who was twice delivered at the full period, and thrice by the induction of premature labour. I requested this pelvis to be placed on the table, but I regret to say it is not there. (A voice in the crowd called out, "Here is the pelvis!" and it was handed to Dr. Lee, who immediately held up Mr. Skey's pelvis in his left hand, and his own in his right, and begged the Society to compare them.) The President desired that they should be handed up to him. Mr. Skey's monster was speedily reduced to its proper dimensions in the face of the Society. (Mr. Skey said nothing.) The history of this highly distorted pelvis, Dr. Lee said, had been fully detailed in his Clinical Midwifery. In 1820 he had been called to deliver the patient, who had been forty-eight hours in labour at the full period, under the care of a midwife. The woman was a native of Manchester. More than three hours were spent in dragging the smaller bones of the head through the pelvis. She had suffered much from pain about the ilia and sacrum during pregnancy, and became unable to walk. Dr. Lee recommended the patient to have premature labour induced if ever she became pregnant again, but the advice was not taken, and in 1832 the late Dr. John Prout was called to this patient when in labour at the full period. From the distorted state of the pelvis, Dr. Prout found it impossible to reach the os uteri with the finger, and thought delivery never could be accomplished but by the Cæsarian operation. The pains being weak and irregular, and no necessity for immediate delivery, Dr. Lee advised delay. About twenty-four hours after the commencement of labour, Dr. Golding and Dr. Lee saw the case with Dr. Prout, and then the orifice of the uterus was felt considerably dilated, and the head presenting. It was resolved to perforate the head to remove the brain, and leave the case for a time to nature. Fourteen hours after Dr. Golding passed up the crotchet between the uterus and head, and fixing its point in one of the orbits, succeeded in dragging the head through the pelvis. The patient recovered, as she had in 1820, without a bad symptom. In the month of June, 1833, premature labour, or abortion, was induced in this patient in the fifth month of pregnancy by perforating the membranes. The fœtus was expelled eight days after, without any artificial assistance, and she recovered in the most favourable manner. On the 12th February, 1835, premature labour was induced in the same patient at the commencement of the seventh month of pregnancy. The fœtus was expelled without artificial assistance, but its head was squeezed so as to be quite flat on the sides. On the 19th January, 1836, when the same patient was at the end of the sixth month of pregnancy, Dr. Lee endeavoured to induce premature labour, by puncturing the membranes. He could not succeed, and this partly in consequence of the forefinger of the left hand being, at the time, nearly deprived of sensation and the power of motion, from a dissection-wound, followed by deep-seated inflammation of the joints. The use of this forefinger had long been completely regained. The effects of ergot of rye were tried without effect. On the 14th of March another attempt was made to perforate the membranes with Mr. Holmes's instrument, but this did not succeed in consequence of the instrument not being sufficiently curved. Dr. Lee had his probe-pointed stiletted catheter constructed, and with this, on the 24th of March, he at once succeeded in drawing out the liquor amnii. The presentation was unfortunately preternatural, and great difficulty attended the extraction of the child, and the patient subsequently died. Had the head presented Dr. Lee had no doubt that the labour would have been accomplished with perfect safety to the mother. In the dwarf at Chelsea whose pelvis was distorted in the highest degree, he and Dr. H. Davies had completed the delivery, and not a single bad symptom followed. Four hours and more were spent in delivering this patient. They took the crotchet by turns, relieving one another when exhausted. The child was literally taken to pieces, and extracted. They were accustomed to call this the Battle of Waterloo, from the condition in which they were left after the affair. To this woman I recommended the induction of premature labour in any subsequent delivery. These, Sir, are not the only cases of the highest degree of distortion in which I have succeeded in accomplishing delivery safely with the perforator and crotchet. Dr. Collins, in a letter written a few days ago, says:—"I have never met with any case where I was not able to effect the delivery without resorting to the Cæsarian section." Dr. Joseph Clarke met with no case where it was necessary. Where it is practicable to accomplish the delivery by any of the ordinary methods, the operation is, in my opinion, unjustifiable. I have seen several cases where it was considered by some, previous to the commencement of labour, that it would be impossible to effect delivery

otherwise, but when strong uterine action set in their opinions were changed. I am now, Sir, fully satisfied that if, in cases of great distortion at the pelvis, abortion or the induction of premature labour were had recourse to at the proper season, no case could occur in which the Cæsarian operation could be required. I have been informed, Sir, that during my unavoidable absence from the Society the greater part of the evening, Dr. Murphy has made some observations on my published tabular view of 127 cases of difficult labour in which delivery was effected by the operation of craniotomy. If accurately informed, Dr. Murphy has stated that I could have had no faith in the induction of premature labour, seeing that I had performed the operation of craniotomy 127 times, and that there had been in consequence, and unnecessarily, a great waste of human life. The details of all these 127 cases have been published in my "Clinical Midwifery," and it is very extraordinary that Dr. Murphy should not have known, and stated to the the Society, that in very many of these cases there was no distortion of the pelvis whatever to justify the induction of premature labour. If Dr. Murphy had ever looked at the table, he would have seen that four of the fatal cases were cases where the operation was had recourse to in consequence of the fœtus being hydrocephalic; that the operation was had recourse to in others, not because there was distortion, but because the uterus had been ruptured spontaneously before I was called to see the patient; that in others there were convulsions, dangerous hæmorrhage, or some serious complication wholly unconnected with the state of the patient. Had Dr. Murphy taken the trouble to look at the table for an instant, he would have seen that in a very large proportion of these cases, before I was called into consultation, the labour had continued from 40 to 70, even 144 hours, and that immediate delivery was required. Had he looked, Sir, at the table, as he ought to have done, before venturing to criticise my practice here, he would have discovered that I had never seen the patients, and knew nothing of them, till the moment I was called upon to relieve them from sufferings, and that when the results were unfortunate, it was because the operation was too long delayed. In no case, Sir, of distorted pelvis with pregnancy, have I failed earnestly to recommend the induction of premature labour. I have, Sir, the greatest faith in the induction of premature labour, and wish, for the sake of humanity, that I could inspire others with the same confidence. I must apologize to the Society for occupying so much of their time. If any gentleman have any questions to put to me, here I am to answer them.

Dr. Webster here rose to mention a case, but the time of the Society being nearly expired, and there being general calls for him,

Dr. West rose, and said, that if, when Dr. Robert Lee had borrowed his paper from him, three days before it was read to the Society, he had asked him only a few questions, how much unpleasantness might have been spared. First, however, with respect to his (Dr. West's) statistics of the Cæsarian section; he had not enumerated in his table any case before 1750, because it was from that time that Professor Kaiser, of Copenhagen, had dated his first case; he (Dr. West) did not think it necesssry to give cases anterior to that date; they might, therefore, be dismissed. There was only one exception to this, the case of Mary Donelly; this he introduced, because he believed that it had been well attested, and had usually been referred to in accounts of the Cæsarian section; two medical men had seen the woman previous to her labour, had seen her also a few days after her delivery, when the incision in the abdomen was shown to them. The child's leg was in the vagina previous to the operation, so that it was either a case of Cæsarian section, or ruptured uterus: under either circumstance the case must be regarded as most remarkable. Mr. Barlow's case had been doubted, in consequence of the extreme tenuity of the walls of the uterus when it was cut into; but Mr. Barlow, in his account of the operation, had said that the liquor amnii had come away, the uterus had contracted, and the lochial discharge taken place. The mere tenuity of the uterus was not sufficient of itself, as it was not so very uncommon as to warrant us in rejecting this as a case of Cæsarian section. Dr. Lee, in his table of this operation, had left off at the 23rd case, but since 1821 there had been four successful cases of Cæsarian section in Great Britain; and the case operated upon by Mr. White, of Manchester, might be added, in which the woman lived until the thirty-second day after the operation, dying then from an advance of the disease in the bones of the pelvis, and not from the operation or its consequences. The Cæsarian section, then, was not so necessarily or so invariably fatal as Dr. R. Lee would lead the Society to imagine. Other cases on the Continent had also been successful, and he (Dr. West) did not see why evidence from the Continent on this subject should be rejected. This was all he need say in answer to Dr. Lee. With respect to the observations of Dr. Tyler Smith, and the expression of his regret that craniotomy had not been attempted in his (Dr. West's) case, he would remark, that it was, he believed, true, that in two cases of softened mollities ossium which had been placed on record, the bones did yield when the instruments were applied, but this was quite an exceptional occurrence, and did not offer a sufficient warrant for a repetition of the operation. If this were attempted and failed, then the subsequent performance of the Cæsarian section was attended with more difficulty and danger. With respect to the absence of any expression of his regret that he had not seen this case sufficiently early to induce premature labour, he might only remark, that he did not expect that opinions would be expressed which had no particular bearing on the paper. For the same reason he had not thought it necessary or proper to enter upon that subject in the essay alluded to by Dr. Tyler Smith. Dr. West then referred to a report of the proceedings of the last meeting of the Society, in the *Lancet*, and said that he did not, in his observations, as reported, say, "that he regretted to think that many practitioners in London appeared to underrate the value and importance of that operation." It did not become him to make any such statement, and it was a mistake to suppose that he had. He had also to complain, in the report, that the expressions against himself had been added to with an ungenerous intensity—thus, Dr. Lee had never used the word "abomination," as reported; neither had he held up the operation as a "striking warning to others."

Other additions and alterations were made to and in the report; it was not for him to, explain or to determine how this had occurred, but such was the fact. In conclusion, he begged to observe, that in striving laboriously to follow honourably in the footsteps of those who had gone before him in his department of the profession, he could not but regard such statements, coming from a gentleman in Dr. Lee's position, as likely to injure him, who was comparatively a young man; and he would appeal to the Society whether such attacks were either generous or just. Hear, hear.)

Dr. Robert Lee said, that he had used the expressions which Dr. West had referred to, and saw no reason whatever to retract a single word that he had employed in the last discussion. He would repeat that the operations, as performed, were abominations.

The President.—Surely, Dr. Lee, you are not justified in using that term in an offensive or personal sense?

Dr. Lee had not used it at all in a personal manner. nor to hurt the feelings of Dr. West, or any other gentleman. He had merely applied it to the proceeding.

Dr. Addison.—As I understand you, you mean that any one holding your opinions on the question of the Cæsarian section would be guilty of abomination if he performed it under the circumstances detailed.

Dr. Lee bowed assent.

Dr. Oldham said, that the observation of Dr. Ashwell, that he regretted that more attempts had uot been made in his (Dr. Oldham's) case to deliver by instruments, surprised him much, for Dr. Ashwell had immediately afterwards said, that in such cases the difficulty of delivery was almost insurmountable. If he (Dr. Oldham) had gone farther than he had done, in his attempts at delivery, he should have let the golden moment go by, and dared not have ventured on the Cæsarian section. Dr. Ashwell's patient had died undelivered; might not the Cæsarian section, if early performed, have been a better proceeding? With respect to the earlier performance of craniotomy, as mentioned by Dr. Tyler Smith, the peculiarities of the complicated presentation which he had detailed in his paper had rendered it impossible to perform the operation before he did.

Foreign Department.

FRANCE.

On the Employment of Chloroform Internally and by Friction in Lead Colic.

Dr. Aran (*Bulletin General de Therapeutique*) has published the results of his experience of the above method of treating painter's colic. He does not profess originality, but on the contrary, admits that he has been anticipated by MM. Blanchet and Grossier. He thinks, however, that he is the first to use the medicine externally, which he considers the most efficacious of the two modes of exhibition. His usual mode of proceeding is to apply a compress dipped in chloroform to the abdomen for the space of twenty minutes, and at the same time to give internally about thirty drops in mucilage, or half the quantity by the rectum. These doses are repeated according to circumstances. He has treated eight cases in this manner, all of which recovered in from two to six days.

On Posterior Luxation of the Phalanges.

M. Michel (*Gazette Médicale de Strasbourg*) has endeavoured to explain why certain dislocations of the phalanges are reducible by very simple extension, while others are reduced with difficulty, or are altogether irreducible. In order to satisfy his mind as to the causes of this difference, M. Michel has artificially induced dislocations on the dead body, and has sought, by dissection, the anatomical peculiarities in each instance. Taking metacarpo-phalangean dislocation of the thumb as a type, he found the following appearances:—

In the instance of an irreducible dislocation, he found the extensor-tendons inflected on themselves, following the outline of the displacement. The muscles attached on each side of the base of the first phalanx were slightly separated, exhibiting the head of the metacarpal bone between them. The flexor tendon was not displaced, but its synovial sheath was extensively ruptured. The anterior ligament accompanied the base of the phalanx, and ran behind the articular end of the metacarpal bone, which it tightly embraced; the lateral ligaments were uninjured. If violent endeavours at extension were made, the ruptured end of the capsular ligament was seen to be pinched between the surfaces of the two bones, so that the displacement was rather increased than diminished. If, on the other hand, prior to making the extension, the joint be opened behind, the impaction of the ruptured ligament does not occur, and the reduction becomes comparatively easy.

In reducible dislocations the changes are very similar, with one important exception,—the anterior ligament is not torn from its metacarpal attachment, but is detached at the base of the displaced phalanx, so that it could not be impacted between the articular extremities of the bones as in the former case.

Thus, according to the author, the difference in the reducibility of these dislocations depends on the condition of the anterior ligament.

Precocious Menstruation.

Instances of the premature development of sexual peculiarities, or supposed to be such, are sufficiently numerous. We say supposed to be such, as it must be doubtful whether instances like the subjoined are cases of true menstruation, or discharge connected with ovular development. M. Marage (*Union Médicale*) mentions the case of a child three years of age, who at the age of thirty-four months, was taken poorly with pains similar to those which precede menstruation, and which were followed by sanguineous discharge from the vagina, which lasted four days, and was in quantity equal to that usually lost by full-grown females. The loss was repeated four consecutive months, after which it gradually declined into a simple leucorrhœa.

Sudden Death from Fright during an Operation for Lithotomy.

M. Cazennave (*Journal de Médicine de Bordeaux*) narrates the following case on the faith of four surgeons who witnessed the catastrophe :—

M. Dubousquet, aged 60, robust and of good courage was the subject of vesical calculus. Having determined on being cut for stone, he was placed in the ordinary position, when as the sound was about to be introduced, he suddenly fainted, and died in a few minutes. [Had chloroform been exhibited in this case it would doubless have been charged with the patient's death.]

The Functions of the Chorda Tympani.

Dr. A. Duchenne (*Ibid*) has investigated the physiology of this nerve; his conclusions are, that it regulates the general and gustatory sensibility of the two anterior thirds of the tongue.

New Property of Chloroform.

M. Augend, of Constantinople, (*Bulletin des Academies,*) has ascertained that chloroform possesses powerful antiseptic properties. This he ascertained by enclosing meat in bottles containing a few drops of chloroform, of æther, and of simple atmospheric air, respectively. He found that in the flasks containing chloroform and air the meat changed to a vermilion red, but not so in that containing æther. At the end of a week that in the chloroform had acquired the appearance of boiled meat, and was perfectly sweet, while the other samples were in a highly putrescent state. It appears that 1-200th part of chloroform will prevent the putrefaction of fresh meat.

GERMANY.

On the Chemistry of Respiration.

Dr. Horn has published the results of his experiments on the chemistry of the respiratory process. (*Neue Medecinisch-Chirurgis che Zeitung.*) The paper is recapitulated in the following conclusions :—

1. The longer air is retained in the lungs, the larger the quantity of carbonic acid contained.

2. The products of expiration undergo a regular hourly variation.

3. The expiration of carbonic acid increases after the ingestion of food or drink.

4. Children and growing persons exhale more carbonic acid than old people; men more than women, and persons of the sanguine temperament more than those of the lymphatic habit.

5. The use of alcohol increases the exhalation of carbon.

6. Pain, sedentary occupations, menstruation, inflammation fevers, are so many causes of the diminution of carbonic acid.

7. The exanthemata cause its increase.

The author offers likewise to demonstrate,—

a. That the act of respiration, tends to the maintainance of animal heat, as well as to the purification of the blood.

b. That the act of respiration is in an opposite ratio to the activity of the renal and hepatic secretions.

c. The oxygen is not the only element of the atmosphere which is taken into the blood, the nitrogen is also absorbed and rejected in variable proportions.

d. Irritability increases in proportion to the amount of oxygen absorbed.

Treatment of Spina Bifida.

M. Nevermann (*Ibid*) proposes four methods of treating spina bifida. The first consists in the employment of galvano-puncture and compression. A needle covered with silk and varnished, is forced into the tumour. The conductor of the negative pole of a battery of moderate power, is brought into contact with the needle, while the other conductor is applied to the skin of the abdomen or chest. The contact is maintained for twenty minutes at a time. The galvano-puncture is followed by the application of a compress.

When this plan does not succeed, the author advises a seton as a substitute for the acupuncture; the compression being carried out conjointly as before. If this fails, the next resource is the injection of the sac with a weak solution of iodine. All these plans failing, nothing remains but to eztirpate the tumour altogether.

Pericardial Friction-sound in Cholera.

Dr. Pleische (*Prägue Viertelsjarhschrift*, 1851,) narrates cases of cholera in which, during the stage of collapse, he heard a distinct friction-sound, similar to that of pericarditis. The patients, three in number, died, but after death there was no exudation observed sufficient to have given rise to the sound heard during life. In one case only there was a white spot on the right ventricle, in the others the serous membrane was preternaturally dry.

General Retrospect.

ANATOMY AND PHYSIOLOGY.

Arrangement of the Cancelli in Bone.—By Prof. Wyman.

The author has stated these general conclusions respecting the arrangement of the cancelli in bones :—

1. The cancelli of such bones as assist in supporting the weight of the body are arranged either in the direction of that weight or in such a manner as to support and brace the cancelli which are in that direction. In a mechanical point of view, they may be regarded as studs and braces.

2. The direction of these fibres in some of the bones of the human skeleton is characteristic, and, it is believed, has a definite relation to the erect position which is naturally assumed by man alone.

In the lumbar vertebræ, which support the height of the body vertically, these cancelli run vertically and

transversely; the vertical fibres directly sustaining the pressure, the transverse bracing them at right angles.

The neck of the thigh bone is adapted to resist pressure by its oval form, the longest axis being vertical, and by the greater thickness of the wall of bone on the under side. Dr. Wyman describes another provision, which consists in having the cancelli of each femur so arranged as to form a segment of an arch or truss, which co-operates with the external shell in sustaining the weight of the body; the necks of the two femora forming opposite segments of an arch. He describes two sets of cancelli; one set rests or abuts on the convex surface of the thick shell, which forms the under wall of the neck, from which they diverge towards the upper part of the head, neck, and trochanter; the other series, arranged in parallel curves, are attached below to the base of the trochanter, and above to the ascending portion of the former series. Both these are braced by others, which run at right angles.

In the lower part of the femur and tibia the cancelli are adapted to support vertical pressure.

On the astragalus the pressure is vertical; but this bone rests on two others; one below it—the os calcis, the other in front—the scaphoid. Within these exist two series of cancelli, directing the pressure on the surfaces of support.

These peculiar arrangements are not found in quadrupeds, and only partially in apes.—*Transactions of the American Medical Association*, Vol. iii., p. 56.

PRACTICAL MEDICINE.

Death resulting from a Biliary Calculus, lodged in the Hepatic Duct.—By Tracy E. Waller, M.D., of Camden. Del.

The deceased was an industrious man, the father of a large family, and highly respected. He had lived until recently in the lower part of this state, and the adjoining part of Maryland—a decidedly "bilious" district. He was fifty-seven years of age, and for many years, according to the statement of his family, had been subject to severe attacks of "bilious cholic," These attacks, the author judges, from the description given of them by his wife, were probably *icterus calculosus*, or similar to the one which caused his death. There was undoubtedly chronic disorder of the biliary organs, at least of the liver, and he had been troubled very much for a long time, with indigestion. A few days previous to his last attack, he had been exposed to inclement weather, and complained of being unwell. The author was sent for on the night of February 24th, 1850, and found him in great pain and suffering. This was mostly in the right epigastrium, though there was some pain and tenderness in the abdomen. On making inquiry respecting his previous health, &c., and, after an examination of his case, the author concluded there must be acute disease of the liver, and probably inflammation of the bowels and their investing membrane. His treatment, of course, was antiphlogistic. The next day he visited him in the morning and evening, and found him to be getting worse. There was evidently extensive peritoneal inflammation, and his strength was failing. The next morning, February 26th, the author being engaged in an obstetric case, sent for Dr. Salsbury, of Dover, who had been his physician for some time previous. This gentleman visited him about nine o'clock and found him in a sinking condition. At eleven o'clock he expired.

The author obtained permission of his family to make a *post-mortem* examination; and about twenty-four hours after death, with the assistance of Dr. Salsbury, the autopsy was made. The *post-mortem* appearances are given in the order of dissection.

Thorax.—Nearly the whole of the right lung was hepatized. The patient had had an attack of pleuro-pneumonia, about fifteen years since, followed by an abscess, which accounts for the condition of the lung. The left lung and pleura were normal. The heart contained a small quantity of serum, and presented marks of recent slight inflammation in the right auricle, otherwise it was normal.

Abdomen.—The stomach was nearly normal, with some inflammation near the pylorus. The duodenum had more than half its surface highly inflamed; the small intestines and peritoneum in the same condition, and covered in many places with yellow bile. The pancreas was inflamed and adhered—there were several adhesions to the folds of the peritoneum. The lower half of the right and inferior lobes of the liver, was much inflamed and indurated. The hepatic duct was highly inflamed, distended, and softened. It was ruptured about one inch from the liver; and just below the opening, contained an ovoid biliary calculus, three-fourths of an inch in length, and a fraction over a half inch in diameter. It must have been lodged there for several days, as by the lymph, thrown out in consequence of the inflammation, it was completely imbedded in the duct. This at once explained the presence of bile in the cavity of the addomen, which had been quite unaccountable, before we came to the duct. It also enabled us better to understand the reason of the great extent of inflammation. The bile was extensively diffused over the bowels and parietes of the abdomen, and the fascia along the linea alba had been tinged by it, of a yellow colour.—*Philadelphia Lancet*, Jan. 1, 1851.

On Fatty Degeneration of the Heart.—By Dr. Begbie.

The author narrates two cases of death from fatty degeneration, being those of Dr. Chalmers and Dr. Abercrombie, after which he makes some remarks on the diagnosis of the affection.

Speaking first of *drowsiness, giddiness, and coma*, he says, that neither of these symptoms were observed, though such might have been expected, if we except an attack of paralysis, which occurred in both cases. But the occasional occurrence of paralysis and apoplexy, in connection with fatty degeneration, may, he thinks, with more propriety be referred to other concomitant lesions.

Faintness and syncope were also not noticed in the two cases recorded, but Dr. Begbie is disposed to admit

that Dr. Chalmers might have died of syncope. He does not, however, regard fainting as diagnostic, since it may be expected to arise when the left side of the heart is deficient in power, whether arising from fatty deposit on the heart, or thinning of its walls by dilatation.

Shortness of breath is a symptom frequent in cases of fatty heart, but was not observed in either of Dr. Begbie's cases.

Præcordial pain is another symptom generally acknowledged by the subjects of fatty heart; this also was entirely wanting in Dr. Begbie's cases.

Functional derangement of the liver has been noticed as a constant attendant on this form of heart disease. Hasse informs us that so far from being a local malady, it is only one manifestation of a general condition of system. In Dr. Chalmers case, disturbance of the hepatic function was a prominent symptom, and the organ was found diseased after death.

The *state of the pulse* cannot be depended upon as diagnostic of fatty heart. In some cases it has been found irregular, in some weak, in others slow. In both Dr. Begbie's cases it was soft and weak, but never irregular. Hence he observes that in neither case was auscultation had recourse to.—*Edinburgh Monthly Journal*, March.

On the Influence of Mercury in the production of Cancrum Oris.—By Dr. Dugas.

The author states that in his district (Georgia) the occurrence of gangrenous affections of the cheeks, lips, and gums, in children, is by no means uncommon, and there are few communities in which there may not be found some living evidences of its havocs upon the face, as well as of the possibility of occasionally preventing a fatal result. He does not know of any satisfactory explanation of the fact that it affects exclusively those of tender years, and most frequently those between five and eight years of age. The object of his communication is to direct attention to a corresponding susceptibility of children of this age to mercurial salivation and sloughing, and to elicit the inquiry into the probable influence of mercurials in the occasional causation or excitation of such a state of things. Without denying, for a moment, that sloughing phagedena, cancrum oris, or gangrenopsis (as the affection is variously denominated) may and does occur in individuals who have never taken mercurials, he inquires whether it is not probable, that the use of an agent which does of itself sometimes induce a very similar destruction of tissues, and which is especially prone to do so at the very period of life most subject to gangrenopsis, may increase the tendency to this disease, if any exist in the system? Having had his attention very early drawn to the danger of giving calomel to children during the period of second dentition, he is disposed to attribute to it the fact, that during a practice of twenty years he has never had a case of gangrenopsis which had not originated in the hands of others. He relates the case of a family of five children, three of whom had during the autumn been successively taken with remittent fever, and died with most awful sloughing of the cheeks and lips. They were all treated with calomel. Discouraged at the result, the parents determined to change their medical adviser, and he was requested to see the other two children when similarly affected with fever. These were treated without mercurials, and recovered without gangrenopsis.—*Southern Medical and Surgical Journal*, October, 1850.

Treatment of Rubeola by Inunction.—By Dr. Evans.

Dr. John Evans, of Chicago, has treated measles successfully by inunction as recommended by Dr. Schneeman in scarlatina, and relates the following case. June 1st, 1851, he was called to a girl 15 years of age labouring under the characteristic symptoms of a violent attack of measles—strong febrile action; severe pain in extremities, loins, and head; injected suffused eyes, with intolerance of light; constant distressing nausea, and the eruption well marked upon the face, neck, and breast. Eight grains of Dover's powder were given every six hours, and there being no abatement of the symptoms the next morning, Dr. Evans directed the patient to be rubbed with a piece of fat bacon over the entire surface.

The relief was marked by the subsidence of all the distressing symptoms in a few hours, and the application was repeated twice the next day. No other treatment was applied except the free use of warm teas. The recovery was more rapid than Dr. Evans had before seen in such cases, and without any disagreeable sequel.

Two other members of the same family were treated by the inunction, with the same favourable results.

Dr. Evans has since used the plan of treatment in a number of cases, and with uniform and prompt relief.—*American Journal of the Medical Sciences*, Jan., 1851.

SURGERY.

Case of Spontaneous Cure of Popliteal Aneurism.—By James Syme, Esq., Edinburgh.

T. M., 35, a seaman, sent from Banff by Dr. Milne, to be under Mr. Syme's care, on account of an aneurism in the left popliteal artery, was admitted into the Hospital on November 18. The tumour filled the popliteal space and pulsated strongly. It was first noticed about six months before by the patient, after lying one night with his leg hanging over the edge of his hammock. He had been either at sea, or actively engaged in harbour duties ever since, and always remarked that exertion was followed by an increase of pain. With the exception of occasional rheumatic pains, he had enjoyed good health.

The patient was kept quiet in bed, with restricted diet and gentle aperients, to prepare him for the operation. In the course of a day or two, the aneurismal pulsation became much less distinct, and could not be felt at all on the 23rd, when the tumour was also observed to be greatly reduced in size, and no longer the source of any uneasiness. On the 9th of December, the patient being completely relieved from the disease, proceeded homewards.

Mr. Syme states that a case precisely similar to the one just related, occurred to him some years ago.

The patient came over from Kirkcaldy, in Fife, where he had pursued his occupation as a weaver until the day he was admitted into the hospital, when the perfect rest there afforded was immediately followed by coagulation, and the other steps of a spontaneous cure. "These facts (he observes) seem to suggest a suspicion that the one or two very rare instances of pressure being quickly followed by recovery, may really have owed the beneficial change to the assistance of the *vis medicatrix*, from rest in the horizontal posture, and not to the effect of compression. Certain it is, that if the two cases just mentioned had been submitted to pressure, they would have appeared triumphant examples of its successful employment. The Dublin writers allege that no confidence can be placed in trials of pressure on this side of the Irish Channel, accounting for all its failures and bad consequences by attributing them, with characteristic frankness, to prejudice and ignorance on the part of the operators. Well aware of this peculiarity in the estimation of evidence, I have calculated the average length of time requisite for the duration of pressure, from the facts supplied by the advocates of this system. In twenty-three cases of aneurism, reported by Dr. Bellingham, from the practice of seventeen surgeons, as successfully treated by pressure, I find that the average duration, not of the treatment, but of the actual compression, excluding the intervals of its discontinuance, amounted to thirty-eight days. Thirty-eight days and nights of misery, to escape a few minutes of trivial uneasiness!

"If the cases treated in the Dublin hospitals since the publication of Dr. Bellingham's work, have been more protracted than those he has recorded, it would be well to acquaint the profession with them. But if this be done, I trust that the results of *all* cases will be given, together with a full statement of the means required to render the patients able to endure the prolonged torment of compression."—*Monthly Journal of Medical Science*, January, 1851.

[Mr. Syme does not take a fair estimate of the treatment by pressure. A careful persual of Dr. Bellingham's cases has led us to a very contrary opinion.—Ed. P.J.]

Rupture of the Crucial Ligament of the Knee-joint.

Dr. Stark relates two instances of an injury, which he believes to have been rupture of the crucial ligament of the knee-joint. The symptoms, nearly identical in both cases, were the following:—There was no dislocation either of the ankle or of the knee-joint; no displacement of the knee-pan; no rupture of the tendo-Achillis, or of any of the tendons round the knee-joint. The motions of the ankle, and, when the patient was sitting, of the knee-joint, in so far as its ordinary motions were concerned, appeared perfect. In one case, when the patient assumed the erect posture, the knee-joint was found to be preternaturally moveable; and, whenever any weight was endeavoured to be thrown on the right leg, the knee fell against the leg, and *bent with equal facility forwards or backwards.* When the legs were extended, the slightest pressure on the patella caused the foot to be thrown upwards, *and the leg could be bent forwards on the thigh to a certain extent.* No pain was complained of in the knee-joint, but only a sensation of weariness; and there was no redness, nor swelling, nor effusion of blood.

Dr. Stark made several trials on the first patient, to ascertain the accuracy of the diagnosis. When the knee was bound tightly with a handkerchief, and kept slightly bent, the patient could almost bear the weight of the body on it; but the moment he endeavoured to straighten the limb, *the knee bent backwards under him*, and he fell to the ground unless supported. The lateral motion of the tibia on the thigh-bone, though freer than usual, was yet so very limited, that there was no reasan to conclude that the lateral ligaments were injured.

The treatment consisted in fixing the limb in a nearly straight position, just so slightly bent as to allow the flexors of the leg to have a slight advantage over the strong extensors attached to the patella. A strong flat steel spring, fourteen inches long, with a slight curvature, was softly padded, and bound to the back of the knee-joint, half of its length projecting down the back of the leg, half extending along the back of the thigh. The foot and leg, to above the knee, were then bandaged moderately tight. The injury was ultimately recovered from in both cases; but the knees remained weak, and the patients had to use support for a considerable period. In one case it was five months, in the other three months and a week, before the use of crutches could be dispensed with.

Dr. Stark thinks these cases interesting from their rarity, and from their proving that the injury in question may be perfectly recovered from. He infers, that cure must have been finally effected by a reunion taking place between the ends of the ruptured crucial ligaments.—*Edinburgh Medical and Surgical Journal*, and *London Journal of Medicine*, December, 1850.

MIDWIFERY.

Ovarian Tumours; Adhesions.—By Dr. Tilt:

Dr. Tilt states that partial peritonitis and consequent adhesions are of very frequent occurrence, although a better knowledge of ovarian disease permits us to consider as exaggerated Dr. Seymour's opinion, that adhesions exist in ninety-nine cases out of one hundred. In a table constructed by Dr. Tilt, we find that—

Adhesions existed in	.. ..	62 cases.
„ absent in	.. ..	41 „
„ not mentioned in	.. .. ..	76 „

The extent of such adhesions is variable, from slight filaments scattered here and there, to complete adhesions of the cyst. They may be soft and readily broken down, or dense and grating under the finger. They are evidently the product of inflammation, but this is sometimes of so mild a character that it is unaccompanied by the slightest pain, while often no adhesions are found where tenderness has existed for a lengthened period. Dr. Clay thinks that tapping favours adhesions, but Dr. Bird, and others, have not found

this to be the case. Dr. Ramsbotham is of opinion that adhesions may bring on a favourable termination, by binding down the cyst, and preventing its further development; but this is a very exceptional case.—*Medical Gazette*, January 31.

UNIVERSITY OF CAMBRIDGE.

NATURAL SCIENCES TRIPOS.

CAMBRIDGE, MARCH 8TH, 1851.

Gentlemen who distinguished themselves and passed their examination March 8th, 1850:—

First Class.—Distinguished in Chemistry: Living, St. John's College; Harden, Magdalene College.—*In Physiology and Botany:* Hort, Trinity College.—*In Chemistry and Botany:* Evans, St. John's College.

Second Class.—Payne, Trinity College; Wilson, Trinity College.

This being the first year of the Natural Sciences Tripos the number of candidates was small.

QUESTIONS.

Comparative Anatomy.—1. Describe a primitive organic cell. In what respects are the simplest Infusoria analagous to such a cell, and in what does the analogy fail? In Infusoria having a mouth, are there any visible actions which correspond to the distribution of nutrient fluid, and to the aeration of the same? In what different ways are their motions performed? How are they propagated? How do you distinguish them from microscopic vegetable forms?—2. What are the anatomical characters which distinguish the Bryozoa from the Polypi? Mention some genera of the former class. —3. Acalephæ: What is the situation of the organs supposed to produce the sensation of stinging on touching many of these? Describe their form. What do you consider to be the respiratory organs in this order? What are the metamorphoses between the states of ovum and of full development.—4. In those star-fishes which have only a single opening into the digestive cavity, and in those which have an outlet from it also, what difference is there in the origin of the cœcal appendages?—5. Describe the typical ring of an animal of the Articulata (sub-kingdom). What are the appendages of such a ring? In those which breathe by gills or tufts, where are these attached?—6. What are the anatomical characters which distinguish winged insects from the class Arachnida on the one hand, and from the class Crustacea on the other?—7. Describe the six parts which enter into the composition of the masticatory apparatus of Insects (organa cibaria). Compare these different parts, and shew how they are modified in form and office in the Coleoptera and the Haustellata.—8. From the general economy of Insects, shew that it is at least as probable that the Malpighian vessels, or tubes, perform the office of a kidney as of a liver. State direct chemical experiments which determine the question.—9. Vertebrata: Describe the typical Vertebra, according to Professor Owen, defining its autogenous and exogenous elements. Shew how these elements make up a vertebra of a bird in the thoracic region.—10. What are the modifications of the spinal column in birds which relate to flying? Describe the bones which make up the frame-work of their shoulder.—11. What is the position of the Pancreas in birds: what the ordinary number of its ducts? How is the limit between the small and large intestine generally indicated in this class? Is it the rule, or the exception, that birds have a gall-bladder. Give instances of the exception. When there is a gall-bladder, what is the number and course of the ducts between the liver, bladder, and duodenum?—12. Have birds any of the following parts of the brain? Pons, lateral, lobes of Cerebellum, Fornix, Corpus callosum.—13. Mammalia: On what characters and their combinations is Cuvier's division of Mammalia into orders founded? What is it which properly constitute *the hand?*—14. Which of the following possess a clavicle: Whale, Kanguroo, Mole, Shrew, Horse, Rhinoceros, Hedgehog, Seal, Bear? What Mammalia have a persistent coracoïd bone?—15. How are the Larynx, Epiglottis, and Nasal passages modified in true Cetacea to fit them for aerial respiration, whilst feeding with the mouth under water?—16. What are the osteological characters of the Æthiopic, the Mongol, and the Caucasian races of man.—17. What are the peculiarities of the human brain?

Physiology.—1. Give illustrations, derived from observation on different animals, of the law that the more developed and complicated the individual parts of an organism are, the more dependent are they upon one another.—2. Give instances to prove that the modes, in which the excitable properties of organs are manifested, depend not on the nature of the stimuli, but on the peculiar vital endowments of the organs themselves.—3. Shew that in animals which have distinct, circulatory, respiratory, and nervous systems, the reciprocal action of these is necessary to life.—4. Give instances of fluids either at rest or in motion in contact with living surfaces being under the influence of the vital forces with which those surfaces are endowed. Assign the proofs of the existence of such influence.—5. What are the chief alimentary proximate principles in the food of man? State the tissues of the body with the constituents of which some of these principles more especially correspond.—6. What part, in the process of assimilation of the food, is performed by the agency of the stomach in vertebrate animals? and what forces are concerned in that agency?—7. What changes occur in the chyle in its course from the latcteals of the intestines to the termination of the thoracic duct in the vein?—8. Describe the mechanism and function of respiration in mollusca, batrachia, and insects.—9. In what consists the analogy between respiration and ordinary combustion? and how do you explain the generation of animal heat in the system generally?—10. Explain the physiology of hybernation.—11. What purpose does the tortuous course of the internal carotid and vertebral arteries subserve in man? State cases in the lower animals in which remarkable arteries assume the form sometimes called "rete mirabile," and explain the purposes supposed to be effected by them.—12. Trace the analogy between growth and secretion by reference chiefly to recent physiological observations.—13. Distinguish the absorbing function of the veins from that of the lymphatics, and support your statement by reference to experiments. —14. What are the elementary constituents of fat? what purposes does it serve in the animal œconomy? and what place in the scale of animalized substances would you assign to it?—15. What is the characteristic property which, according to Haller, is inherent in the muscular fibre? What are the principle facts alleged in proof of the existence of such inherent property? and according to his theory how is the nervous system related to it?—16. What are the functions respectively of the superior and inferior laryngeal nerves, as shewn by the experiments of the late Dr. J. Reid?—17. What do you understand by reflex or excito-motory action in the nerves? In what parts or organs of the human body are its phonomena principally manifested?

Chemistry.—If 1 lb. of Steam at 212° be passed into 100 lbs. of water at 60°, what will be the resulting temperature.—Describe and give the theory of Leslie's process for making Ice.—2. Explain the formation of dew, and the apparent radiation of cold. Can heat of

low intensity be refracted to a focus?—3. Describe the principles and process of Electrography, and the decomposition of Water by Voltaic Electricity.—Distinguish between true Electrolysis and secondary decomposition. 4. How may the chemical equivalents of Carbon, Sulphur, and Nitrogen be determined; those of Oxygen and Hydrogen being known?—5. Fifty grains of Oxide of Copper. reduced by Hydrogen, give 11.35 grains of Water: what is the atomic weight of Copper; Hydrogen being unity?—6. What quantity of Nitrate of Barytes will decompose 100 grains of Sulphate of Soda; the atomic weights of Barium and Sodium being 70 and 24? —7. Express by Symbols the decomposition of one equivalent of Phosphate of Soda by three equivalents of Nitrate of Silver.—8. Give a general formula for Alum Salts; and examples of Chemical Types. Does the Electro chemical theory accord with that of Types? —9. Give Tests for the Sulphuric, Nitric, Hydro-chloric, and Phosphoric Acids; and a formula for the combination of Potash with Oil of Vitriol considered as an Hydrogen Acid.—10. Describe a process for the Ultimate Analysis of Organic Substances including Nitrogen.—11. What are the Tests for Starch, Gum, Resin, Gelatine, and Albumen; and for the Oxalic, Tartaric, and Hydrocyanic Acids?

Botany.—[*N.B.* The questions are arranged in two divisions, and those in the second division will be given out after the expiration of the first hour, which is to be devoted entirely to the questions in the first division of the subject.]

1*st. Division. Chiefly Morphological, Anatomical, and Physiological.*—1. By what characters (structural, chemical, and vital) are plants most efficiently distinguishable from animals?—2. What are the proportions (or nearly so) in which the equivalents of the elements entering into the composition of Cellulose and Protoplasm are supposed to be combined?—3. What are the organic compounds (and how are they constituted) which more immediately result from the action of the vital processes carried on in the cells?—4. Give Schleiden's view of cell-formation. Have any very essential modifications of it been suggested by the later observations of eminent Microscopists?—5. To what general laws are the arrangement of leaves (Phyllotaxis) subjected, whether in their normal or metamorphosed conditions?—6. Explain the origin and modifications that take place in the arrangement of placentæ.—7. What peculiarities are observable in the tissues of Coniferæ?

Botany.—2*nd. Division. Chiefly Structural and Systematic.*—8. Contrast the terms employed in describing the original position and parts of ovules (at the time of impregnation) with the terms used in designating the ultimate position and parts of the seed in the matured fruit.—9. Describe the general characters of the fruit of Papaveraceæ, Euphorbiaceæ, and Umbelliferæ, remarking any very peculiar modifications to which they may be subjected.—10. Give the essential characters of the following orders: Malvaceæ, Cucurbitaceæ, Chenopodiaceæ, Orchidaceæ, Juncaceæ.—11. How do you distinguish Solanaceæ from Scrophulariaceæ? Are there any genera whose positions may be doubtfully assigned to the one or the other of these orders? 12. Describe the plants and fruits lettered *A, B, C, D, E, F;* strictly confining your replies to the following particulars, so far as they may be observable.—(*a*) *Leaf.* Arrangement; Stipulation; Degree of composition; Form; incision. —(*b*) *Inflorescence.* General character; Bracteal appendages.—(*c*) *Flower.* Peculiarities of Calyx; Corolla; Stamens (insertion, &c.); Disk; Pistil (Ovary, Style, Stigma, Placentation).—(*d*) *Fruit.* General character; Dehiscence; Placentation.—(*e*) *Seed.* Arrangement; Reasons for assigning a peculiar character to the Embryo, if it be not present, or not very distinct. —(*f*) Is there any reason for supposing the plant would not be found in the Linnean class and order to which it might strictly be referred?—(*g*) To what natural order does it belong? What are the essential characters of that order?—(*h*) Do the species of the above order generally affect any peculiar "stations"? Are they mostly "endemic" or "sporadic"? And in what "Regions"?

Mineralogy.—1. Define the terms 'simple form' and 'combination.'—How many faces have each of the varieties of simple forms in the rhombohedral system? —What is the law of symmetery in the rhombohedral system?—2. Mention the number and situation of the planes that divide symmetrically a crystal belonging to the pyramidal system.—3. Arrange the collection of models of crystals placed upon the table according to their systems.—Point out and name any hemihedral forms you may happen to observe among them.—4. To which system do the crystals of the majority of the metals belong? Enumerate the exceptions.—By what processes have crystals of the metals been obtained in the laboratory?—5. What do you understand by isomorphism? Is the term strictly or only approximately correct? Give an example of isomorphism in each of the systems of crystallization.—The crystals of $As\ O^3$ belong to the cubic system, those of $Sb\ O^3$ to the prismatic system. Are these facts reconcilable with the theory of isomorphism?—6. Describe an experiment made by Mitscherlich which appears to account for the fact that crystals frequently contain isomorphous elements in all proportions.—7. What is a "pseudomorphous" mineral? Give some examples of pseudomorphous minerals.—8. Describe the scale of hardness adopted by Mohs, and the method of applying it to determine the hardness of any mineral.—Can different parts of one and the same crystal exhibit different degrees of hardness? If so, give examples.—9. Draw a figure of a crystal boracite exhibiting a combination of the faces of the cube, dodecahedron and octahedron.—By what peculiarities are the faces of the octahedron marked in crystals of boracite? —Give an account of the thermoelectrical properties of boracite?—By what names have Riess and G. Rose distinguished the thermoelectric poles at which vitreous and resinous electricities respectively appear during the process of cooling?—10. Describe the appearances seen when a crystal of blue or red sapphire is viewed in a direction perpendicular to its axis, through Haidinger's dichroiscope.—11. Give an account of the magnetic properties of bismuth.—12. Describe methods of distinguishing scolezite from mesotype.—13. Name the minerals marked *A, B, C,* &c., stating your reasons for supposing them to be the minerals so named.—Mention the systems of crystallization to which they belong.—Point out the twin crystals that occur among them.—14. Enumerate the essential constituents of the following minerals, and mention the systems of crystallization to which they respectively belong.—Analcime, apatite, aragonite, beryl, diaspore, felspar, gahnite, greenockite, leucite, malachite, realgar, topaz.—15. Give the formulæ expressing the chemical constitution of the following minerals:—Fluor, hematite; magnetite, cinnabar, orpiment, olivine.—16. By what metallic oxides have the globules of borax α, β, γ, &c., been coloured?—17. —Describe methods of detecting the following substances when present in a mineral:—Chlorine, fluorine, phosphoric acid, sulphuric acid, potash, soda, barytes.—18. The analysis of a mineral gave silica 24·99, oxide of zinc 68·66, water 7·75; compute its chemical formula, having given that the quantities of oxygen in 100 parts of silica, oxide of zinc and water are 51·96, 19·74 and 88·9 respectively.

[We have inserted the above examination papers as likely to interest those who have relations educating at Cambridge. The remainder shall be given in the next *Journal.*—Ed. J.]

Medical Intelligence.

THE SALE OF ARSENIC.

Lord Carlisle's Bill to regulate the sale of arsenic, now in the House of Lords, has been printed. It declares that the unrestricted sale of arsenic facilitates the commission of crime. The bill provides, that on every sale particulars of the sale shall be entered by the seller in a book before the delivery of the arsenic, and every such entry is to be signed by the person selling the same. Any person selling arsenic, save as authorized by this bill, and persons giving false information to obtain arsenic, are to be summarily convicted before magistrates, and to be liable to a penalty not exceeding £20. The bill is not to prevent the sale of arsenic in medicine under a medical prescription. A recent case caused the introduction of the bill.

CÆSARIAN SECTION.

Now that this operation is being warmly discussed in the profession, the following extract from *La Presse Médicale de Bruxelles* may be interesting:—"A woman, who had already borne several children, has just been delivered by the Cæsarian section with complete success. The patient, who lives at Anendonk, in Belgium, was attending to her household affairs on the twenty-ninth day after the operation, which was performed, with much skill and dexterity, by M. Bruggeman, assisted by M. Willens. The child lived only a few hours" It is a pity that we are not told the exact amount of deformity which rendered this fearful operation necessary.

EPIDEMIOLOGICAL SOCIETY.

On Monday, the 3rd instant, the fourth ordinary meeting of this Society was held at the house of the Royal Medical and Chirurgical Society, in Berners' Street. Officers having been nominated for the ensuing year, Dr. McWilliam read a paper "On the Yellow Fever Epidemy in the Brazils, in the year 1849." The paper contained many strong illustrations of the contagious nature of this disease, which, in the spirited discussion which followed, were combatted by Mr. Baker, a visitor, who appeared to doubt the validity of the evidence on which the author had adduced some of his most important facts. The question assumed an interest and importance which was considered sufficient to warrant an adjournment of the discussion to the meeting in April.

CHELTENHAM MEDICAL BOOK SOCIETY.

The members of the Cheltenham Medical Book Society have just presented their Honorary Secretary with a handsome silver Etruscan claret jug, bearing the following inscription:—

"Presented to William Philpot Brookes, Esq. M.D., by the Members of the Cheltenham Medical Book Society, as a token of respect and esteem for his valuable services as their Honorary Secretary."

APPOINTMENT.

Mr. George Elin, late House-surgeon of King's College Hospital, has been appointed House-surgeon to the Birmingham General Hospital.

ROYAL COLLEGE OF SURGEONS.

The following gentlemen were admitted members on Friday, the 7th instant:—Thomas Allen, London; Henry Bullock, Reading, Berkshire; James Weston Coombs, Canon Street; Edward Emra Earle, Westbury-on-Trym, Wiltshire; Frederick Ellis, Birmingham; Edward O'Callaghan Foott, Cork; Charles James Grant, Arundel, Sussex; Robert Hamilton, Maddox Street, Bond Street; Thomas Wm. Joseph Marsh, Australia; John Griffith Morris, Liverpool; William Stewart James Home Munro, Caithness, Scotland; William Peck, Sharnbrook, Bedfordshire.

SOCIETY OF APOTHECARIES

The following gentlemen received certificates to practise on Thursday, Feb. 27:—William Fanshaw, Haslingden, Lancashire; Nevill Jackson, Stamford, Lincolnshire; Henry Walker, Ludlow, Salop. Gentlemen admitted on Thursday, March 6:—J. Carruthers, Dumfries; William Dewsnap; Richard Driver Kidd, Godalming; Ebenezer Moore, London.

OBITUARY.

Feb. 9, Thomas Parker, Esq., aged 68, M.R.C.S., and one of the senior apprentices of the late John Abernethy, Esq.

Feb. 12, at Bentinck Terrace, Regent's Park, John James Bowie, M.D., aged 31. Dr. Bowie was the son of Captain Bowie, R.N. Several years since he was elected one of the assistant-physicians of the Hospital for Consumption, which office he resigned about a year ago, on account of being seized with the disease which eventually terminated his existence. This disease proved to be phthisis pulmonalis, though it assumed a different character in its commencement.

Lately, Assistant-surgeon Stuart, of the Cape Mounted Rifles, killed in action with Sandilli's Caffres, at the Keiskamma River, while under the command of Colonel Mackinnon.—Off the coast of Africa, Mr. Symonds, of the *Kingfisher*.—At Sierra Leone, Staff-Assistant-surgeon Watson.—At Cephalonia, Brownson, Staff-surgeon Ford, 2nd West India Regiment.—At Dublin, Assistant-surgeon Reed, 4th Dragoons.—Assistant-surgeon Ligertwood, Veteran Battalion.

BOOKS RECEIVED FOR REVIEW.

General Index to the first 33 vols. of the Medico-Chirurgical Transactions. Longmans, 1851.

Queen's College, Cork. Introductory Address on Medical Education. By Alexander Fleming, M.D., &c, Dublin, 1851.

TO CORRESPONDENTS.

Communications have been received from Mr. Newnham, Dr. Cormack, and Mr. Giraud.

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho. But all communications respecting the routine business of the Association should be forwarded to James P. Sheppard, Esq., the Secretary of the Association.

It is also particularly requested that all post-office orders should be sent either to the Treasurer or Secretary, who alone have the power of giving receipts.

CLINICAL LECTURES

ON THE

PRACTICE OF PHYSIC,

DELIVERED IN THE

THEATRE OF QUEEN'S COLLEGE, BIRMINGHAM, 1849-50.

By DAVID NELSON, M.D.,

Physician to the Queen's Hospital, and Professor of Clinical Medicine, &c

[Reported by MR. WILLIAM ROGER BANKS, Student of the College and Clinical Clerk.]

LECTURE III.

On the Morbid conditions of the Brain and Nervous System, and of the Organs of Sense. (Continued.)

I shall now take a general review of those more purely nervous affections of an acute kind which partly involve the brain and partly the spinal prolongation. I pass over mania, self-delusion, and the other morbid actions of the mental faculties and feelings, as these belong to a certain class of hospitals, and a certain class of practitioners exclusively. They find no place either in ordinary hospitals or in ordinary practice, and we had better therefore not speak upon subjects with which we have no means of being practically acquainted; I shall confine myself, therefore, to those bodily affections traceable directly to some disorder of the nervous system, in which involuntary action takes place of greater or lesser magnitude, with or without a loss of mental consciousness. These consist of a rigid contraction called spasm, or of an alternate contraction and relaxation called convulsions, and are exemplified in the diseases known under the specific names of hysteria, chorea, rabies, epilepsy, tetanus, and common convulsions. The essential pathological feature in all these diseases consists in the presence of some irritant which reacts on the cerebral and spinal or ganglionic centres, so as to excite within them an uncontrolled activity of their reflex powers, and the essential treatment, therefore, consists in removing the irritant cause, and abating the mental or nervous sensibility.

Hysteria is a complaint which assumes a thousand Protean forms, and simulates almost every organic disease of the body. I shall not enter in detail into all the symptoms of a disease so familiar, but shall merely observe that they consist of sudden manifestations, partly emotional, such as the inclination to laugh, to weep, to sigh, or to scream, without any adequate cause, and partly reflex, as the convulsive motions, or the shifting pains that fly hither and thither, though frequently fixed as a permanency in the left side. The large evacuation of limpid urine is one of the chief pathognomonic signs of a regular fit, and in the fit there may be any degree of mental alienation from perfect consciousness with excitement, to perfect unconsciousness. The usual exciting cause of an actual fit or paroxysm of hysteria will generally be found to be excessive rage, or jealousy, or vehement and ungratified sexual desire, along with certain conditions of the uterus and stomach, such as hyperæmia, or sub-acute inflammation, which have the effect of rendering the general nervous system exceedingly sensitive. The arrest of this acute paroxysm is usually to be effected by agencies which shall break down and obliterate from the memory the more sentimental causes of the excitement. Such are the authoritative expostulations of some one who is held in respect. The dashing of cold water without ceremony over the body, the administration of the most offensive antispasmodics, the application of sharp sinapisms, or indeed any other mode of treatment that shall recal the attention from an unsubstantial to a substantial source of uneasiness. Such are the modes of procedure that might be resorted to among those rougher specimens of the sex who may accompany a military or naval force, or who may be found in prisons, workhouses, &c.; but among the more refined, where the fits are not so great a hinderance to the positive and necessary duties of life, we are generally content with lulling the sensibilities by means of castor, opium, or chloroform, in the consciousness of the disease not being a very dangerous one. So much for the actual paroxysm.

I next direct your attention to that milder exhibition of the complaint which we so very frequently see in hospitals and elsewhere, and which I would name chronic hysteria. This consists in low spirits, with sighing, and occasional fits of shortness of breath, indigestion, flatulence, anomalous pains, shifting hither and thither, but mostly fixed in the left side, along with excessive or defective menstruation, or subacute hyperæmia of the uterus, leading to fluor albus or congestion or other derangement of that organ. The shortness of breathing in such cases will sometimes lead us to the suspicion of phthisis, but the frequent sighs contradict that symptom; and if the spirometer be persevered in, as a test, for some time, it will be found that though the expirations again and again be of small amount, yet at one time or other they will measure such a bulk as to dispel all idea of any physically diminished capacity of the lungs. An equally substantive and still more amusing proof consists in this:—that the same person, who, on detailing her ailments, can scarcely speak for want of breath, will yet on being excited scold her husband, her child, or her attendant, with a depth of lung, and length of sentences, truly Ciceronian. The pains may also be mistaken for inflammation or rheumatism, but the shrinking and crying almost before touch, and the forgetfulness of the agony when the attention is withdrawn from it, afford clear proof of hysteria, though it may often be necessary to treat the pain as if it were an organic one, and by blistering, or the application of a seton or potassa fusa, to give them something real to think about, and to dispel all leisure for vain imaginings. Such cases are to be encountered according to the form of the symptoms. Where evidence exists of a determination of blood to the uterus, with white or red discharges, we must resort to astringent injections, or to local abstraction of blood, according to the extent of the evil If redness, or indu-

ration, or ulceration of the os uteri exist, or any other diseases, which I shall treat of when I speak specially of that organ, then the remedies for such diseases will be applied. Excess or diminution of the catamenia must have their appropriate remedies, the first in cold bathing, and the salts of lead, with opium; the second in iron and other emmenagogues, coupled with warm bathing. The remedies to allay the nervous irritability are tonics, stimulants, and antispasmodics,—such as arsenic, iron, bismuth, or zinc, with ammonia, valerian, or assafœtida. To abate that morbid sensibility of feeling which leads to constant depression, with a tendency to tears when spoken to, and pains in the stomach, &c., I have found nothing to equal the virtues of musk and castor, though in some obstinate cases, (as in that of Sarah Brown,) opium may prove the most available agent, to be administered according to necessity. Combined with all these means we must also enjoin a nourishing and simple diet, out-door occupation, and cheerful diversion of the mind—in short the tonic regimen. No order of complaints will more annoy and baffle the physician than this of hysteria, and he always must dread engaging with its fickle and shadowy eccentricities as much as he delights in contending against the real and regular march of some more deadly malady. In chorea we have something more tangible to combat with, and therefore have much more satisfaction in the efforts which we make, even although they should ultimately prove unsuccessful. The essence of the affection is some irritating influence acting on the ganglionic system, conveyed thence to the spinal chord, and there giving rise to those eccentric excitements of the motor force which produce the involuntary wrigglings and contortions which give the disease its name. The seat of the primary irritation is almost always in the abdomen, and generally confined to the bowels or uterus. There will be great constipation; and there may be retention of the catamenia. The liver will generally be found to be in a very torpid condition, and the stools passed will have a pale ashy hue. The first obvious symptoms may be merely slight twitches of the muscles, and some dragging of the limbs, which will gradually increase until the patient loses almost all voluntary force whatever, lying prostrate in bed, powerless, and dejected, yet tormented with incessant tossing of head, trunk, and limbs, contrary to inclination. Between this extreme, and the slight twitchings already alluded to, there may be every gradation of disturbance, as it must of necessity be modified by the degree of visceral irregularity, and by the strength or weakness of the patient's natural will, the exertion of the latter being always a great aid in the cure after the more physical causes have been removed. As to congenital chronic chorea, it is almost to be considered as beyond the reach of treatment, but the acute chorea is to be boldly grappled with, and the remedies to be persevered in till it be subdued. Head symptoms, such as dilatation of the pupils, with fretfulness, will sometimes manifest themselves, and then those decided measures of local leeching and blistering, &c., already inculcated, will have to be resorted to. The main objects to be pursued will be the removal of irritant causes by anthelmintics, and by purgatives of more or less activity, the moderation of nervous excitement by sedatives, the renewal of the natural secretions by specific stimulants, and the restoration of muscular or nervous tone by those metallic tonics which are known to invigorate the motor system, act how they may. And here I would draw your attention to what I consider an example of unreasonable and dangerous scepticism on the part of an eminent physician, Dr. Marshall Hall. Speaking in his "Croonian Lectures" of the cure of diseases of this kind, he says:—"The mind must be preserved free from agitation. The blood, if impaired, must be restored to its healthy condition; dental, gastric, enteric, and uterine irritation must be avoided" Then, he adds:—"*If ever* trial may be made of empirical remedies, such as silver, zinc, copper, the valerianates, indigo, cotyledon, sumbul, an issue in the arm, &c., *ad infinitum*, all which, like mesmerism, homœopathy, &c., act by inspiring confidence in the patient's mind. But all this is, in reality, untruthful, derogatory from, and unworthy of, our profession, and belongs to the low art of quackery and imposition." Now, this language is so strong, that I cannot permit it to enter your ears without pointing out at the same time how weak is its argument. If by empirical remedies Dr. Hall means those agents which are recognised as causes of certain effects, though we cannot discover the bond of union between such cause and effect, then the sentence simply means nothing at all, as the observation in that case is applicable, not to those remedies only, but to every occurrence in nature. But if he uses such an expression in its offensive sense, and means to convey, as I think he does, that such agents merely act through an impudent imposition on the imagination of the patient, and that bread crumb or distilled water, would be equally efficacious as silver, zinc, &c., if conjoined with the mere confidence of the sufferer, then the assertion must be plainly denied, as erroneous and hasty in the extreme.

We know for example, as a certainty, by illustration of numerous cases in this hospital, that the exhibition of silver alone, followed by a saline purgative, has at once arrested epilepsy, &c., by effecting the expulsion of worms. This metal was used by Boerhaeve, and is mentioned by Sydenham in relation to such parasites, and has been recently revived with like intent, by Mr. Whittal of this town. The trials of it in this hospital by Dr. Birt Davies and myself, have been most satisfactory in their results. But while in certain cases the worm is actually expelled, in others there can be no doubt that the animal has been killed, though not known to be evacuated, inasmuch as all the constitutional symptoms have afterwards disappeared, whether they consisted of itching at the nose, &c., or dyspepsia, or chorea, or epilepsy. Now, in the latter disease, silver has long been used with good effect, though with no suspicion of its killing a worm; in like manner several of the other remedies have been employed usefully though with no exact knowledge of their mode of acting. Zinc, silver, castor, &c., do most certainly allay mental and bodily irritation, and give tone to the

system, and so have earned for themselves the names of tonics and antispasmodics: the ignorance of their manner of action nowise affects the matter of fact which is palpable to every observer, except such puzzle-headed speculators as are ever looking for nicer explanations than they are doomed to obtain. No doubt such explanations are worth seeking after in proper time and place by the most diligent experiment, but we are not to withhold from acting on the known facts, until our uncertain researches after the unknown come to a close, which might be never. If, indeed, such dreamy notions ever come to influence our profession generally, we should soon degenerate from our high calling into a mere fraternity of babbling idlers, habitually permitting our obscure hypothetical doubts and quibbles to interfere between the suffering man and some ready means of cure. For no greater evil could overtake mankind than such a refusal to use the means to an end, until they should understand the intricate manner of Nature so affecting it; such conduct would not only put zinc, silver &c., into the shade, but exclude from use almost every item of the materia medica, and even food itself. So distorted is the idea, that those who hold it can only rank with the quidnuncs mentioned by Dr. Samuel Johnson, who would profoundly require the reason why a cat's tail was long and a rabbit's tail short, &c. In offering these remarks you will perceive that I have not sought to make any wanton attack upon the author alluded to, but simply seek to defend myself and the profession at large, who have employed and do employ such agents as zinc, silver, valerian, &c., from such hard imputations as quackery, imposition, untruthfulness, and the like. The direction of your minds in matters of practice has been so far confided to me, and I am therefore anxious to prevent your imbibing so noxious a principle as this, emanating as it does from an influential writer, who is commonly so subtle and exact. And to confirm your sounder views the more, I shall quote to you at length the sentiments of the philosophic Sydenham on the same subject, propounded under somewhat similar circumstances. He says:—"And now I have delivered my sentiments on this disease (small-pox), which are deduced from practical observations, and not from a groundless hypothesis: and in reality I cannot conceive how a person should be mistaken, who directs and confines all his reasonings to the practice of the art or science which he intends to learn and exercise with reputation; and on the contrary, how it is possible that he should do anything but spend his life in idly deceiving himself and others who employ his time in searching after such things as have not the least relation to practice, and as he would be no honest and successful pilot who were to apply himself with less industry to discover and avoid rocks and sands, than to search into the cause of the ebbing and flowing of the sea, which, though well-deserving the attention of a philosopher, is quite foreign to him whose only business is to secure the ship; so neither will a physician, whose province it is to cure diseases, arrive at a perfect knowledge of the art of medicine, though he be a person of genius, who bestows less time and application in investigating the hidden and intricate method of nature in producing and nourishing diseases, (whereon their histories also depend), and adapting suitable remedies thereto, than in curious and subtle speculations that do not at all contribute to snatch the patient from imminent death, which is the intent of the healing art, And this delusory procedure does not only deprive mankind of these singular advantages which would accrue to them from the ingenuity of many physicians, but renders the art of physic rather the art of discoursing than of curing; and 'tis come at length to this issue, that the patient must live or die as the philosopher conjectures, right or wrong, which must ever be highly precarious, inasmuch as the first inventors of speculations contended as warmly about their fanciful opinions as those did who blindly followed them, and it may be, none of them in the right. For though by much attention we may be able to discover what Nature does *in fact*, yet the *manner* of her operating will always remain a secret to us. Nor is this strange, since it is infinitely more propable that we poor mortals who are shut out from the glorious region of light and life, cannot possibly comprehend the method which the allwise Creator used in framing the body, than an unskilful smith should be ignorant of the manner of making a clock, the structure and motion whereof manifest the greatest delicacy of the art; and so, though it does evidently appear that the brain is the region of sense and motion, and the repository likewise of thought and memory, it is nevertheless, impossible that the mind should ever be so far enlightened even by the most exact inspection and consideration thereof, as to understand how so thick a substance, and a kind of pulp, which seems not to be very artfully formed, should suffice for so noble a use and such excellent faculties. Nor can it be accounted for from the uature and structure of its parts, how any particular faculty comes to be exerted thereby." Such are the strict logical rules by which we must be guided, or else we shall flounder into all the sophisms and quiddities of a barbarous age. Paradoxical as it may sound, such scepticism and credulity are usually twin brothers, and it must be obvious that he who has come to doubt the existence of himself has equally reached the extreme of the one and the other. But to return to the subject; there will seldom be any eccentric action during sleep, but sometimes sleep will be very limited so that the patient (as in the case of Mary Dearne, fol. 29) will be almost exhausted to death. In the instance just referred to it will be observed that there was at first no great degree of constipation, so that tonics and sedatives were the first agents applied, and afterwards a mild aperient pill. Some days after a bowel complaint set in, which so far from ameliorating the symptoms, magnified them to a very alarming degree. Under the circumstances all the other medicines were stopped, and she got nothing but laudanum till sleep should be induced. This gave some relief but induced an opposite condition of the bowels; and on reference to the case, it will be seen to what an enormous amount various powerful purgatives had to be administered before evacuation was effected.

Thus she took successively four grains of calomel four times; two ounces of castor oil, half an ounce of oil of turpentine every hour for six times, then one drop of croton oil every hour for six times, and all to no effect until I ordered a clyster, consisting of one ounce of oil of turpentine, and one ounce respectively of sulphate of soda, sulphate of magnesia, and muriate of soda, while extract of belladonna was applied to the constricted sphincter ani. There then came away a vast discharge of dark and offensive matter, but after that the stools being pale, they were kept natural and evacuated freely by means of the ox-gall and aloes, from which period all the symptoms gradually disappeared under the liberal use of the sulphate of zinc, which seemed to prove more efficacious than the nitrate of silver previously used. It was a severe case, but recovery was effected within forty-six days, a period considerably less than a patient is often doomed to suffer, even under energetic treatment. Amongst the means of rousing the peristaltic action of the bowels and improving digestion, the ox-gall is not to be reckoned as the least, as it not only appears to act as a substitute for the human bile, but also to excite the natural secretion, so that after a long period of pale or variegated discharges, requiring constant laxatives and occasional mercurials, this agent will not only improve the colour and regularity of the fæces for the time, but even induce a permanent sufficiency of the secretion, after a brief course of it. Where chorea is dependent on a stone in the kidney, or softening of the cerebellum, or other obstinate and persistent cause, as suspected in the case of Griffith, of course it is less tractable.

On rabies I shall say little or nothing: as originating in so subtle and minute a poison, requiring so long a period of incubation, and being so invariably fatal, its history possesses much interest, but as no cases have presented themselves in our hospital, and as I myself never saw one, I shall not enter into the question at large. The poison, like most other foreign matters taken into the system, has a particular determination to parts. It is chiefly manifested on the frame, and appears to affect the general nervous system, so as to give rise to an universal exalted irritability beyond that of any other disease. The whole of the reflex chain is commonly affected, but more especially, perhaps, the medulla oblongata and the upper portion of the chord, or that portion which has been called the respiratory track, by Sir Charles Bell, but which ought more properly to be termed the digestive, inasmuch as respiration is only one portion of that great process. It will be observed, in reading accounts of this disease, that those organs are most affected to which the pneumogastric nerve is supplied, and some *post-mortem* inspections have proved an inflammatory condition of the medulla oblongata. The first idea that presents itself, in considering the treatment, in the absence of all knowledge of a specific kind, is naturally that of the employment of sedatives to allay so extraordinary an irritability; nevertheless, both these and other agencies have been employed in the most amazing doses, such as opium, to the extent of an ounce, without any apparent effect. Chloroform has, I believe, subdued symptoms, but only to return after its withdrawal; so much indeed has the materia medica been exhausted in these experimental trials without success, that I am disposed to think we need scarcely look for the cure of this disease. After it is lighted up by any line of treatment, the chief attention should, therefore, be turned to the neutralization of the poison before it has induced such a condition of body, and to the prevention of its elaboration. It has been asserted that no dog which has had "the distemper" will take it without direct infection. It would be well if this were tested and confirmed, for if it were the fact, we could then have the power of almost annihilating this dreadful malady.

Epilepsy is distinguished by the sudden loss of sense and voluntary motion, the victim falling down with more or less convulsion, especially about the face, while he emits a froth from his mouth which is frequently tinged with blood. In true epilepsy there is such total unconsciousness, that not even the pupil is sensible to a brilliant light, and this will always distinguish the real from the affected fit. When severe, it will more resemble apoplexy than anything else, the difference being that the first, like its causes, is temporary, whereas the second is more permanent. The peculiar causes of epilepsy are usually hereditary, and are rather of an obscure kind. In some we can trace the existence of spicula of bone within the cranium, which, when the circulation is calm tend to no pressure, but whenever it is excited, so that an overplus of blood is carried to the brain, there exerts their pressure, and so the fit seems to be induced. The same explanation embraces scrofula and other tumours in the head. In others we may find a natural tendency towards engorgement of the brain, under the slightest mental or bodily irritation, arising from pressure or dyspnœa, or indigestion, but without the presence of any permanent physical formation. In others, again, we have to fall back on the more vague supposition of an arrest of the nervous current depending on causes of which we know nothing at all, but which are called into existence from time to time under different irritations, which may even produce their effects during sleep. Besides these hereditary, or congenital causes of this disease, it is also known to have been induced by severe blows on the head, or other affections of the brain, or the presence of worms, or retention of the menses. In such instances the patients and their relatives may have been entirely free from such attacks, yet subject to them ever after, so frequently and increasing in number and severity, as at length to end in fatuity.

The individual fits need not excite much alarm, as they are seldom fatal; but one great source of anxiety must ever attend the epileptic, in the fear of his having the seizure at some time or other in a dangerous place, such as a steep stair, or beside the fire, or deep water, or a precipice, or any other situation in which his loss of consciousness might involve a probable loss of life. Such patients ought, therefore, to be carefully watched. A long continuance of such fits, however, must be fatal to existence, especially if the patient be exposed to

strong causes of excitement, such as an active civil or military life in men, or pregnancy and parturition in women. Obstetric practitioners know how disagreeable is its visit in the latter condition; and so much is to be expected from the former that, as you are aware, the ancients called it morbus comitialis, on accouut of its frequent occurrence in their stormy popular assemblies. Some of the victims have no warning of the attack; others have several premonitory symptoms, which enable them to take care of themselves, such as a sense of pain, coldness or palpitation, or that singular creeping sensation which has been called the aura epileptica. Such are the chief features connected with epilepsy. During the fit we can do little or nothing besides protecting the patient against himself, especially as regards biting the tongue, &c., and waiting for a return of sense. Then the treatment must depend on what appears the probable cause. If on spicula of bone, or depression, or malformation of the skull, or the pressure of any suspected tumour, or other source of occasional pressure, then we can simply seek to moderate the force of the circulation by enjoining habitual abstemiousness, with rest; the avoidance of stooping, and all excitement. If upon congestion, then we must have recourse to local abstraction of blood, and purgatives, along with that quietude of demeanour and use of tonics which most represses excitation. When purely nervous, tonics and antispasmodics must be conjoined; and when arising from physical injury, or the presence of worms, or restrained excretions, then we have to remove these causes of irritation by means of the remedies known to be effectual in such cases; and as shall be more particularly pointed out under their respective heads. When dependent on a fixed organic cause, we can only hope to moderate the fits. When on worms or on congestion, we have better reasons to hope for success; and when the attacks are of a functional kind only, we have every ground for believing that they may be effectively obviated by the employment of metallic and other tonics with good regimen. Thus we find hysterical and other persons of nervous constitution become subject to fits of epilepsy simply from seeing others so affected. In such cases the greatest benefit will be derived from the use of iron, zinc, and silver, especially the two latter, if we conjoin with them a good plain diet, with stomachic bitters, exercise, and diversion, and cold bathing, if the season will permit. Most of the cases under my supervision in the hospital have been those of out-patients, in which the proper regimen could not be properly enforced; yet only one of them resisted the powers of zinc and silver, which I therefore view with great reliance.

We have now to consider the nature and treatment of spasm. Tetanus is the name given to the most formidable manifestation of rigid contraction which can possibly take place, and which often involves the whole muscles of the body. In the synthetical views, however, which I wish to take of morbid action, it would be manifestly absurd to divide and sub-divide the same diseased condition into so many orders according to the mere degree of severity or its different seats or causes. Therefore, I shall make no distinction between a common slight spasm, and trismus, and tetanus, or whether the one or the other be idiopathic, or traumatic, or opisthotonic, or emprosthotonic, or pleurosthotonic, except as modes or degrees of the abnormal contraction, but treat the whole as one affection of continued spasm, subject to the same principles of treatment in all its phases. We have numerous varied instances of this particular action of the muscular fibre, from the slightest contraction of a single muscle to those of a finger or toe, of the arm, of the calf of the leg, or of the neck, back, or abdomen, or diaphragm, &c., up to the more formidable contractions of the muscles of mastication or deglutition, or of the entire muscular system of the body. These will all be found to depend upon a more or less permanent irritation of the excitory nerves, and a more or less permanently sustained action of the moving nerves in correspondence. These irritating causes may either exist at the periphery of the sensorial system, or in the cerebro-spinal or ganglionic centres themselves. In the first case the disease would be said to be symptomatic, and in the second idiopathic; yet both alike must arise from an excitement at the centres; and the distinction, therefore, is without a difference, so far as a correct theory is concerned. The irritating causes may consist of positive mechanical injury to the more sensitive nerves themselves, or of foreign or crude matter in the more sensitive viscera, or of poisons circulating in the blood, and of a morbid condition of the blood itself, especially its deoxidation, and also in hyperæmia of the spinal chord and its appendages. The strange and terrible forms sometimes assumed by this disease are calculated to strike the spectator with horror. What is called trismus, or lock-jaw, is equally curious, though not so startling as the universal tetanus. In the former we have the muscles of mastication, &c., only affected, with fixation of the jaws; but in the latter we have all, or nearly all, the muscles of the body involved, and leading to effects of a most alarming character. As I already observed, we have had this complaint divided into opisthotonos, emprosthotonos, and pleurosthotonos, and that more equal form of it called the erect. But the truth is, that all are one affection, and the difference of outward form is only due to some accidental weakness of one part of the body as compared with the other. If the muscles in front be the more powerful, or the body be inclined that way, then the head may be bent forward so as to touch the toe. If the contrary should be the case, then the head is bent backwards on the toes, with retracted muscles of the face and starting eyes, so that the sufferer resembles some hideous demon playing the mountebank by forming the letter O in his own person. Should the patient have entire or partial hemiplegia, or any marked weakness on one side, the curvature will be lateral. If his powers be very equally balanced, he will be rigidly erect, like a steel poker. The tetanic form of the disease, therefore, is the more fearful in its aspect; but yet it is not so singularly interesting, in a physiological point of view, as simple trismus, because we can much more easily understand how a distant irritation, in the great toe for

instance, should give rise to such an excitation of the whole spinal chord as would induce an universal spasm of the muscular system, than we can unravel those delicate and mysterious inter-neural communications, through which the same distant irritation shall affect only that limited group of muscles situated about the jaws. There can be little doubt, however, that in man, as in all other animals, there is a peculiar universality of connection between the primary digestive opening and the rest of the body. We know, in the very lowest forms of animal being, that there will be an œsophageal nervous ring if there be any nervous structure visible at all. So in man the close connection that is known to subsist in this quarter, between the voluntary, semi-voluntary, and involuntary nerves that govern the muscles of mastication, deglutition, and respiration, tends to constitute this one of the most important regions of the body; and to unite it, perhaps, more with the whole of the three systems, viz., the cerebral, spinal, and ganglionic, than any other tract of the body whatever; other minute chains of actual communication with the most distant parts will doubtless be elucidated by future anatomists. In the meanwhile, certain peculiar actions indicate that such is the fact, though it may not be physically demonstrable. In the new-born infant this group of muscles acts in full perfection from the beginning, whilst all others not strictly involuntary require experience and education for their proper employment. It is also to be observed in after life that the masseter and other muscles seem to have a more immediate sympathy, as it is called, with the efforts or suffering of remote parts of the body than any others. They are always excited to strong contraction whenever the other muscles greatly exert themselves, or when they are under much pain, or when the mind is wrought up to strong resolution. The setting of the teeth, therefore, is always indicative of powerful action or passion involving the general frame. Thus, being peculiarly connected with the whole physical and moral machinery, it is no wonder that these muscles often might and do become deranged in their functions, under some extraordinary stimulus in remote parts, even when the other muscles of the body remain unaffected. It may be said that every portion of the body is connected with the rest; but yet there are some more immediately and universally in relationship with the whole; and of these, perhaps, the nerves and muscles of the face, &c, stand first. Hence, in all probability, the manifestation of trismus as a local disorder supervening upon a seemingly remote cause.

As to treatment, I have only to repeat the general rule, that we must seek to remove the irritating cause and subdue sensibility. The slighter and more limited forms of spasm that are exhibited in a few muscles here and there, will usually be found to proceed from the accidental circulation of venous blood in the parts, on account of some temporary obstruction to the flow and return of the fluids, as intense cold, or a sudden change of temperature, or a constrained position, or the presence of a ligature, such as a tight garter, or tight lacing. This may be rapidly subdued by a removal of the causes and the use of friction, or if these be not sufficient, a small dose of opium in combination with mercury. Where they are of a more serious description, and dependent on correspondently serious causes, our proceedings must be more decided. Should it arise in a greater or lesser degree from a tear or crush of the flesh, or any other surgical wound, which will most likely be in a finger or toe, or other seat of sensitive nervous expansion, then the most probable means of success will consist in a timely division of the injured nerve, along with purgatives and other powerful sedatives which are applicable to every case—such as opium, or even tobacco. If foreign or crude matters be suspected in any of the viscera, then these must be expelled, whether from the stomach by emetics, from the bowels by the most active purgative or vermifuge, or from the womb by the removal of the placenta, or other existing causes. If poisons are circulating in the blood, such as lead or strychnia, they must be neutralized or expelled by agents suited to act on such particular poisons. If the blood itself be universally in a morbid condition, as in cholera and the like, then our treatment is much more difficult, and must be partially directed to a renovation of the healthy secretions by every means which the circumstances may suggest, and which are too numerous to be classified in detail now. Should the affection more obviously depend on a hyperæmic state of the chord itself, our reliance must be on local abstraction of blood, followed by blistering from the neck downwards to the sacrum, also a liberal use of mercurials and antimonials, coupled with purgatives and sedatives as in all the other cases. In the more severe forms of the disease, however, all of these remedies unless having some early effect, that is to say within four or six days, are likely to prove unavailing, the bodily power then becomes exhausted by the agonizing exertion made by the muscular system, delirium follows upon want of sleep and mental torture, and at length, distortion of the muscles of respiration cuts off what little vitality remains, by inducing orthopnœa and its fatal consequences. A *post-mortem* inspection will most probably reveal a deoxidised state of the blood, with or without an inflammatory condition of the spinal chord or peripheral nerves, according to the origin or nature of the spasmodic action. As tetanus, in all its varied shapes, is a continued spasm or contraction, so convulsion consists of temporary spasms or contractions, alternating with relaxation. These may exhibit themselves in every degree, from the violent commotions of hysteria, chorea, and epilepsy, to the weakly twitches of nervous fever, or the little tremors and shiverings that arise from dissipation, mercury, or long-continued cold, &c. In the former the entire muscles are affected with great vehemence, while in the latter there seems only a short twittering of the minute fibrillæ, *i.e.* short as applied to those fibrillæ individually, but prolonged as applied to the general muscular system; for while one set of fibres are resting, the others are keeping up the irregular action. As all these arise from the same causes which have been already indicated under former heads, I shall not enter much further into them in this place.

They may arise from any irritation conveyed to the nervous centres; and so we have the convulsions of infants, from crude food, &c., of parturient women, from the presence of the child, or placenta, or lochia, and of ordinary persons from other similar causes. They may likewise proceed from idiopathic affections of the brain or chord, and the treatment will vary according to all these causes. The convulsions of infants, which are perhaps the most common, are generally to be subdued by calomel and the warm bath, better than by anything else; but should they depend on the pressure of a tooth on the gum, or the presence of a thorn, or such other cause, of course the treatment must be directed to the affected quarter. For the management of puerperal convulsions, I must refer you to the professor of midwifery; and as to those that affect the ordinary class of patients, under such innumerable forms of irritation as general practice will present, I must simply content myself by remarking that you must endeavour to discover the exciting cause, abate or remove it, and administer antispasmodics, stimulants, tonics, or sedatives, according to the general condition of the system. Thus in purely nervous convulsions, without any apparent physical cause, you may have recourse to such a sedative as opium, or to such antispasmodics as valerian or musk, or to the more potent tonics—zinc, arsenic, and quinine; or when they arise from congestion and languid circulation, you will employ such diffusible stimulants as brandy and ammonia. The presence of irritants will, of course, require a different mode of procedure in the first instance, such as the employment of emetics, purgatives, and vermifuges, or emmenagogues, or other agents, according to their nature, followed up by the stimulants, antispasmodics, or tonics, as they may be required.

February 25, 1851.

REMARKS
ON THE
CÆSAREAN SECTION, CRANIOTOMY, AND ON THE INDUCTION OF PREMATURE LABOUR.

By T. RADFORD, M.D., F.R.C.P., Edin.,
etc., etc., etc.,
Consulting Physician to the Manchester and Salford Lying-in Hospital.

Most of our ablest obstetric writers recognize the Cæsarean section. Smellie, Leake, Aitken, Forster, Denman, Sims, Alex. Hamilton, Clark, Burns, Hull, Gooch, James Hamilton, Blundell, Barlow, Hopkins, Montgomery, Churchill, Shackleton, Conquest, &c., have treated upon it in their writings, and justly consider it the appropriate operation to meet and overcome the difficulties of those cases of protracted labour, for the management of which no other plan is available, or has yet been devised. It ought not to be considered by the profession as a resource solely to save the infant, as some of the observations of its recent advocates imply: but it ought most assuredly to be also valued as, and undertaken for, the purpose of likewise saving the life of the mother. This is a noble object to aim to attain; and if it is duly estimated and tried for, it will most assuredly be accomplished. Its numerous advocates have the highest obstetric reputations, and their opinions will be revered, when the dogmas of its adversaries are buried in oblivion. There is, then, sufficient reason for the existing members of the profession to coolly and deliberately "weigh it in the balance," and if found (not by prejudice) wanting, then they are warranted to expunge it from the obstetric code. To listen to and be guided by dogmatic assertions, is not the legitimate and scientific method to settle questions of life or death. It is a controversial subject, and will remain so, until the evidence *pro* and *contra*, is fairly examined. Most unwarrantable epithets have been used as characteristic of its termination. Dr. Osborn admonishes us as to "the propriety of never exposing the very valuable life of a mother to absolute destruction by the Cæsarean operation." The erroneous doctrines inculcated by this writer, have been ably and satisfactorily controverted by Dr. Alexander Hamilton, (Letters, &c.,) and Dr. Hull. Mr. Simmons justifies the term "inevitable destruction," used previously by Osborn; and further, brands the operation as *murder*. The fallacy of his malignant remarks are ably proved by Dr. Hull. The memorable case of Elizabeth Thompson, upon whom my valued relative Mr. W. Wood performed the Cæsarean section, affords ample proof of his unprincipled objections against this operation, and also his unwarrantable confidence in the *crotchet, and his proposed compound operation.*

This poor woman resided at Hazelhurst, about eight or nine miles from Manchester. When in labour, she was visited by Mr. Ogden, who was also a strong anti-Cæsareanist. After having examined the state of the pelvis, he sent for Mr. Simmons. When he (Mr. S.) visited the patient, he found to his great mortification, that neither the crotchet nor his compound operation were adequate to the delivery of this poor creature. He left the woman without affording her any assistance, and she was afterwards brought over in a cart to the Manchester Lying-in Hospital. The pelvis is in my possession, and a cast of it was presented by me to the Royal College of Surgeons of England. (*Vide* Case, "Medical Memoirs," by Mr. Wood.)

It has been called a "terrible," "inhuman," "cruel," "barbarous," "bloody," "horrible," "murderous," "undesirable," "dreadful," an "unnecessary," and an "unjustifiable operation," it is said to be a "melancholy catastrophe," and "that the operations, as performed, were abominations."

Many cases of protracted labours from distortion of the pelvis, have frequently occurred in my practice, some of which have been terminated by the natural efforts; some by the forceps, and others required craniotomy. Five of these cases required the Cæsarean section, which are quite sufficient to enable me to judge of the contingent circumstances which happened during and after the operation, and authorize me to

state whether the beforementioned terms are warrantable. It is not inevitably destructive, as in two out of the five cases the lives of both mother and infant were saved; it is not a cruel or inhuman operation, because it has been in every case undertaken with the most humane and sympathizing feelings, and with the hopes of rescuing the unfortunate creature from long suffering and impending destruction; it is not a barbarous procedure, being recognized by the best obstetric writers in all civilized countries, as the only available resource to meet the extreme difficulty of such cases; it is not a bloody operation, for in none of these cases was there much blood lost; it is more terrible, horrible, and dreadful to the witnesses of the operation, than to the poor suffering woman herself; she hails with joy any plan which promises to terminate the anguish she has so long endured. Dr. Sims says:—"Human imagination can hardly conceive anything more dreadful than the distressing anxiety of a woman in the pangs of labour, without hope of delivery." It cannot be murderous: to be so, it requires *malice prepense* on the part of the operator; on the contrary, it is done to save two lives. Such an epithet is more appropriate for the crotchet operation. We agree to say it is an undesirable operation, and we hope no man is so wanting in moral principle as to desire such a case to happen in order to gratify his "rage for cruel and bloody operations." The justice and necessity of this operation will be proved in the course of this paper.

A very eminent obstetric practitioner has lately remarked, that "he is fully satisfied that if, in great distortion of the pelvis, abortion, or the induction of premature labour were had recourse to at the proper season, no case could occur in which the Cæsarean operation could be required." Craniotomy or embryulcia are said to be equal to the delivery of some, if not all, the cases of distortions of the pelvis in which the Cæsarean section has been performed.

These several methods, which are recommended to supersede this procedure, do not all stand on the same moral and professional grounds. The induction of abortion, and the induction of premature labour, are considered equal to prevent the Cæsarean operation ever being required, even in the most distorted pelvis. Under such circumstances we are recommended to adopt this practice; nay, I should think, from the tone of the author, either the one or the other procedure must be had recourse to, if the practitioner desires to discharge his duty to his patient. This injunction is not alone confined to those cases with which the practitioner must of necessity be acquainted; at least, that there positively exists a considerable diminution in the pelvic diameters from his experience in former labours; but it is considered that this practice is applicable and ought to be adopted under such circumstances in first labours.

These statements naturally suggest to the mind an important question,—Whether there are any certain indications of the existence of extreme pelvic deformity during the early period of a first pregnancy, which demand manual examination? The pelvis may be extremely deformed in early life by rickets, and although the disease has been arrested, yet the mischief inflicted on its bones continues, and its diminished diameters bear the same relative proportion to its present degree of development which they did to that at an earlier period. In such a case, extreme distortion of the pelvis may exist through the whole period of life, without the slightest external evidence, either in its bones or other portions of the osseous system; and therefore this state can only be ascertained when labour has commenced.

Internal exostosis may grow from any of the bones of the pelvis, without a suspicion that such a disease exists. These tumours acquire different sizes; sometimes they become so large, and diminish the pelvic diameters so much, as to render the Cæsarean section necessary; and yet, until labour has happened, there were no external marks which shewed that so serious an internal impediment to the progress of the child had previously existed. (*Vide* Case of Cæsarean Operation by Dr. Mc Kibbin, *Edinburgh Medical and Surgical Journal*, Vol. 35.)

Fracture of any of the bones of the pelvis may occur at any period of life; and when they are united, either its inlet, outlet, or cavity, may be very considerably diminished in their measurement. If pregnancy takes place after such an accident, the Cæsarean section may be the only means by which delivery can be effected. This happened in Mr. Barlow's case, and although there was here external evidence that great mischief had been done to the pelvis, yet there was no alternative for this operation; for neither of the obstetricians was acquainted with the pregnancy until called in after the labour had lasted for a considerable length of time. A midwife had been employed in the first instance. But in other cases of this kind of accident which may take place in early life, no external traces of the injury may exist, and the occurrence may not be communicated to the attendant, either from the patient having forgotten it, or not considering it of any importance to make it known to him.

Mollities ossium, as its name implies, is a softening of the bones; and may attack any portion of the osseous system, but the pelvis most generally suffers from its ravages, which produce every degree of distortion in it. This disease is usually slowly progressive, and sometimes remains stationary, except during pregnancy, when it rapidly increases. It very seldom (yet it sometimes) happens that the distortion of the pelvis is so great, in a first labour, as to require either craniotomy or the Cæsarean section for delivery. The usual course of this malady is to produce an additional degree of mischief during each succeeding pregnancy, and thereby rendering necessary a different plan of delivery in each succeeding labour. The obstetrician may and ought to avail himself of the knowledge he has had the opportunity of practically acquiring of the degree of distortion at any previous labour, and bring it to bear on and to guide his judgment as to what method should be pursued during the succeeding pregnancy or labour. An accurate inquiry during one labour, with a careful examination of the pelvis in the early months of the next pregnancy, will be all sufficient to direct him in his

treatment of the case. In a first pregnancy he has not this information, and therefore he stands in a very different position in regard to his professional responsibility. Extreme distortion of the pelvis from mollities ossium may exist, and yet every other bone may be free from disease. The pelvis in Sir C. Bell's case was extremely distorted, but the skeleton was of average height; and the bones, especially the thigh bones, were firm and of full size.

It is true the general health suffers in a greater or less degree during the progress of this disease; and pains, like those of rheumatism, are felt about the hips and lower part of the back, and the patient's gait becomes different, and her stature becomes less.

If a woman, for the first time pregnant, applies for professional attendance in her approaching labour, at the fifth, sixth, or seventh month, and on inquiry she complains of the pains above-mentioned, and the other effects of the disease are to be observed, then there can be no doubt as to the wisdom of making an internal manual examination of the pelvis. But in many cases such an application is not made until a later period of pregnancy; and frequently even then no statement of local pains is made to the practitioner. He may be a stranger to her, and unacquainted with her former gait or stature; and he must, therefore, be unable to make a comparison of her present with her previous state. Women in the lower ranks of life usually employ midwives; and, therefore, medical gentlemen are seldom or ever consulted until the labour has continued for some time, when some serious impediment to its advance is found to exist.

From the previous remarks it is quite obvious that no knowledge of the existence of extreme distortion can be acquired in many of such cases until after the commencement of labour, when suitable measures for delivery can only then be determined on. But even in cases in which this knowledge may be or has been obtained, there is no alternative for the Cæsarean section.

A question will no doubt arise in the minds of those who have not had to manage labours obstructed by distortion of the pelvis,—Cannot a manual examination of the pelvic diameters be made with such mathematical accuracy, and a decided opinion formed, whether the child's head will pass through it?

An accurate exploration of the pelvis is at all times of the greatest practical importance; but notwithstanding the best endeavours are used precisely to ascertain its capacity, there is great danger of an erroneous computation, especially when it is distorted. The manual difficulties are great under all those circumstances, but are more so when the brim has assumed the triangular shape. The examination should not be confined to the brim, cavity, or outlet; but the measurement of every division of it must, as far as possible, be accurately obtained.

When it is intended to induce premature labour we should compute the pelvic space in relation to the size of the fœtal head at the period of pregnancy at which the operation is to be done. So, when craniotomy is decided on (as a rule of British practice) the space must be relatively considered; and at the same time it must be remembered that the reduction of the fœtal head cannot be effected beyond certain limits.

Abortion.—The induction of abortion is one of the operations proposed to prevent the necessity of the Cæsarean section; but in the opinion of the writer it can only be justifiable to have recourse to it in a first pregnancy. (*Vide* "Remarks on the Value of Embryonic and Fœtal Life," *Obstetric Record.*)

But it is not alone on moral grounds that this procedure is considered inadequate to meet such a proposition. It is physically impossible safely to perform this operation in most of the cases of extreme distortion of the pelvis, especially in those which have a triangular-shaped brim.

An experienced practitioner unsuccessfully attempted to destroy the ovum. The woman afterwards died. The pelvis is in my possession, and is an example of the highest degree of distortion from mollities ossium which was ever presented to my notice. Other cases of a similar description are on record, in which the same results happened.

Medicines have been administered to produce abortion in these cases; but the practice is unwarrantable and dangerous. One woman died after taking secale cornutum; but in her case an instrument had been first used. Mrs. Sankey, one of the women (already mentioned) who recovered after the Cæsarean operation, became again pregnant. She took, by the direction of her medical attendant, the secale cornutum and infusion of savine, for the purpose of inducing abortion, but it is said they failed to produce it. In more than a month after its discontinuance she aborted a two months' fœtus; the placenta was detained, secale cornutum was given, on the third day it was reached by the finger and extracted. She died in about five days after the expulsion of the fœtus.

Premature Labour.—Premature labour is to be induced, not so much for the purpose of superseding the necessity of the Cæsarean operation as it is to prevent the use of the murderous instruments—the perforator and crotchet. Whenever the pelvis is so much distorted as to prevent the passage of a full-grown infant without the aid of craniotomy, but will permit one that is premature and viable, this operation must be performed before the end of pregnancy. The longer gestation is allowed to proceed without interruption, the greater chance is afforded to the child to live, but the period at which labour ought to be induced, must depend on the degree of distortion of the pelvis. The great consideration here is, the probability of the birth of a viable infant. Most writers assert that it has not the power of maintaining an independent *post-partum* existence until the seventh month of pregnancy. I venture to differ from this opinion, and do not unconditionally accept this limitation, but I think that a shorter period of intra-uterine life would, in many, if not in all cases, enable the infant afterwards to exist.

I have known one, not larger than at six months, survive, and another, not more than six months and a half when born, lived to be ten years of age. Cases are recorded of viable infants born at the above-mentioned periods.

The performance of this operation is justifiable on moral grounds, and it is sanctioned by every professional and social principle. Its object is noble, it saves a life which must otherwise be destroyed, and at the same time the woman incurs not much, (from my own experience I can say no,) more risks than those which are contingent on ordinary parturition. But notwithstanding the high value of this operation, it is not warrantable unnecessarily to have recourse to it. Errors (as already stated) in computing the pelvic space may be made. This opinion is corroborated by a case which occurred in the practice of the late Dr. James Hamilton, briefly related by me in the *Provincial Medical and Surgical Journal*, Vol. 2, 1847, p. 404.

The reader is referred for further information on this important subject to Dr. Merriman's Observations, *Med. Chir. Trans.*, vol. 3, p. 123; Dr. Hull's Letters, &c.; Barlow; Dr. R. Lee's "Clinical Midwifery."

Craniotomy.—It has been asserted that delivery can be accomplished by the use of the perforator and crotchet, in all cases of extreme distortion of the pelvis. The following remarks will prove that this statement is not borne out by facts. In some cases of this kind the head could only just be reached, and with great difficulty (to say nothing of the danger) perforated. But this done, the power of the operators ended, all further efforts made to reduce and extract it completely failed. "Awful catastrophe!"

A consultation was held on the case of a poor woman in labour; most of those present were anti-Cæsareanists, and therefore they decided on craniotomy. The head was, with great risk, just opened with the perforator, but every other effort made to deliver this poor suffering creature was unavailing. She was allowed to endure the anguish of parturient pains until the uterus ruptured, and death terminated her agony. The pelvis was greatly distorted by mollities ossium, especially the outlet, and there is no doubt, in my mind, an erroneous and partial measurement had been made; most likely the brim had been only attentively examined. A cast of the pelvis is in my possession.

In one case, after the head of the infant had been perforated, the Cæsarean section was performed, and it was extracted half murdered. "Awful catastrophe!"

In another case, after mutilation by embryotomy, the infant was extracted by the Cæsarean section. "Awful catastrophe!"

Others of a like nature are to be found on record. In many of the women who have undergone the Cæsarean section, neither the os uteri or the presentation of the infant could be felt. Under such circumstances how could craniotomy be done? This is the only operation, recognized and justified by the British profession, which is undertaken with the intention of destroying life. It is only between the value of craniotomy and the Cæsarean section that a comparison need be made. I have been anxious to undertake this important inquiry, and, as statistic deductions are so much in vogue at the present day, I put out a letter in the *Provincial Medical and Surgical Journal*, October 17th, 1849, requesting the members of the Association to kindly send me a statement of all the cases of craniotomy which had happened in each of their practices; but, sorry I am to say, only three or four gentlemen have had the candour to communicate information on this subject. It has been said that the statistics of the Cæsarean section are worthless, but how, I cannot understand. Those of craniotomy are completely valueless; hundreds of such cases have been silently consigned to the grave. Instead of trying to explode the Cæsarean section, (as now practised in Great Britain, which the foregoing observations prove cannot be done,) we ought rather to endeavour to extend its adoption. I stand fearlessly forward as an advocate for its performance, not only when the woman cannot be delivered by craniotomy, but also in other cases. I consider that the Cæsarean section should be approved as an operation of election, and not, as it now is, one of necessity; and that craniotomy ought to be received in the reverse order.

For a further exposition on these subjects I beg to refer the reader to "Remarks on the value of Embryonic and Fœtal Life," *Obstetric Record;* Letters, *Provincial Medical and Surgical Journal*, Oct. 3, 1849, Oct. 17, 1849; "Successful Case of Cæsarean Section," *Ibid.*, August, 1849; "Cases of Cæsarean Section," *Edinburgh Med. and Surg. Journal*, Vol. 55, page 67.

To have entered more fully on these subjects would have extended the paper beyond the space which is allowed in a periodical publication upon whose pages there is such a great demand.

ABUSE OF THE MICROSCOPE,

AND ON THE

TENDENCY OF THE DIFFERENT BRANCHES OF SPECIAL SURGERY TO DEGENERATE INTO QUACKERY.

By J. INGHAM IKIN, Esq., F.R.C.S., Leeds.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—The use of the microscope is so general, and the benefits it has conferred upon medical science are so universally acknowledged, more especially in relation to the study and advancement of that important and interesting branch of anatomy, termed general anatomy, that it may seem somewhat inconsistent in one who happens to be a teacher of that science, and who has been in the habit of using the instrument and pointing out its discoveries for several years, to speak of its excessive use, or rather abuse. But, may we not say, fashion makes fools in too many instances, besides those wherein the manners and tastes of the public are concerned. Favourite hobbies may be ridden too hard,

peculiar theories may be carried to an absurd extent, and special medicine, special surgery, and special humbug, may serve to retard the progress of pure science and scientific practice, as well as disgust the honourable truth-seeking practitioner of his art. I affirm that, in our profession, this is much too often the case, and having just had my attention called to a case in point, I cannot refrain from sending it to the *Journal*, along with a few hasty comments arising out of the subject.

A patient of mine, married, of a nervous, excitable temperament, was liable to attacks of irritation of the mucous membrane of the bladder and urethra, attended with a sensation of burning and painful micturition, and occasionally with a mucous discharge, but free from any gonorrhœal affection, or from any exposure to infection. He had occasion, during his absence from home, to seek surgical aid in London, but as his attack resisted treatment, and continued much longer than usual, he was not content with consulting either one or two surgeons of high standing, but was induced, at the recommendation of a friend, to consult a gentleman with M.D. to his name, and who professes to make spermatorrhœa his peculiar speciality, (I am ignorant whether he is recognized in London as a legitimate surgeon,) who writes a book or pamphlet on the subject for the perusal of the public, making use of a foreign author of deserved celebrity, gets his work reviewed in the daily newspapers, and succeeds in driving a fair trade out of weak-minded, credulous individuals. I must add, that my patient had suffered before marriage, and several years ago, from syphilis, and was just the person a clever trickster and experienced quack might gull to any extent. Well, to this party he forthwith goes, he unfolds his history and tells his symptoms: the penis is examined, a small portion of the secretion of the mucous membrane of the urethra is immediately collected upon a glass, at once it is placed under the microscope, *exhibited to the patient*, and explained as being in an unnatural and diseased condition. "Spermatorrhœa exists." His habits when young have been the cause of it; his health is on the point of being permanently injured and sacrificed; his virile powers destroyed; and nothing can save him but this god of health he has lately resorted to—this restorer of healthy manhood. The poor credulous patient hears his new adviser, full of faith, admiration, and astonishment, and dreams of spermatorrhœa (for he brings a work on the subject away with him)—this woeful cause of all his sufferings. Supposing this opinion was true, common sense and the ordinary instincts of our nature, should have sent the poor fellow home to his wife and ensured a simple every-day remedy. Such is the abuse to which one of the most splendid adjuvants of our art is exposed! I must also state that this "microscopic abuser" went a step further, and succeeded in frightening my poor patient almost out of his wits, so much so, that the idea of committing suicide even crossed his mind, for he told him that he was suffering from decided secondary symptoms, and that in all probability his wife would, sooner or later, suffer, and his children be diseased, (though he had two fine healthy children,) for I must in candour and fairness state, he was suffering from a cutaneous affection—a species of lichen to which he was liable, and which was rather inveterate. He had to leave town before his cure was effected, and fortunately, soon after he had got into such dangerous hands, so that a tale of woe indeed I had to hear on his return into the country, and it was with the utmost difficulty I could stagger his faith in the correctness of the opinion of the party he had consulted. In order, however, to set his mind at rest, and to destroy his fearful foreboding and unfounded alarm, I recommended him on his return to London to consult Mr. Erasmus Wilson for his cutaneous affection, &c.; (and here, allow me to add, and I have pleasure in doing so, that I consider Mr Erasmus Wilson to be a most scientific trustworthy investigator of the pathology of the skin, and unhesitatingly affirm his classification of its diseases to be the simplest and most correct extant, as it is founded entirely on anatomical principles, and it is the one I recommend to the student who wishes to master the subject.) Mr. Wilson confirmed my opinion, and pronounced the cutaneous affection *non*-syphilitic, and I hope he has, ere this, got the credit of curing him.

In thus strongly expressing myself with regard to this case I by no means wish to inculcate that spermatorrhœa, or the diseased condition so ably treated of by Professor Lallemand, under the head of "Involuntary Spermatic Discharges," is not a disease well worthy of investigation and scientific treatment. Quite the contrary; for it is too well known to the profession that early vicious habits may lay the foundation for organic disease as well as constitutional debility. But to investigate the discharges in an ostentatious, if not disgusting way, *before* a patient is to my mind the very essence of quackery and abuse; and men who live by preying upon the morbid fears of their patients deserve the contempt of every properly-constituted mind; and it becomes a duty to the public as well as to our profession to expose and denounce such illegitimate and unfair proceedings.

But alas for our noble art! it is not the microscope alone that gets into improper hands, and is fairly degraded by the use that is made of it. Are there not many other branches of special surgery exposed to the same degradation? Is not, or rather has not, the the mania for the use of the speculum uteri been an abuse? Luckily for the credit of the profession, the late brilliant discussions on its merits, use, and abuse, before the Royal Medico-Chirurgical Society and the London Medical Society, have rather given a check to its indiscriminate use; though they will not serve to lessen or depreciate its proper value when made use of by competent persons. But that its use is so frequently required, as some parties urge, is a gross abuse that deserves the severest censure. Is not the rectum bougie a fine weapon in the hands of accomplished or unprincipled empirics? How many thousand fees have been unfairly earned, if not obtained under false pretences, from the unwary, the timid, and the credulous, by these sturdy champions for the exclusive claims of the rectum—a term allow me to add, awfully abused—for those who so heroically and exclusively deal with it prefer the *crooked* to the *straight* path with a vengeance.

How often do we hear of your great rectum lights presenting themselves sword (that is, bougie) in hand to almost every patient that consults them; declaring, whilst they sheath it up to the hilt, that to pass the flexures of the rectum and reach the sigmoid flexure with their flexible weapon is (as they tell us) the summit of surgical art—the consummation of anal skill! But, Sir, as there is no accounting for the different tastes of mankind, so we must presume that giving the mind to this particular department alone is but the act of the zealous surgeon, the philanthropist, and the philoshpher! May my good star point elsewhere! and may my reputation and that of the members of the profession to which I belong, never be founded on any such contracted bottom! Forgive the *double entendre.*

It is not my wish wantonly to offend the feelings of any one; but I unhesitatingly affirm that the use of the bougie, both that for the rectum and the urethra, is oft grievously and shamefully abused by men calling themselves legitimate and honourable practitioners.

To turn to another department of special surgery—your oculists and aurists. How few of these confine themselves to legitimate practice! How few are content with addressing themselves to the profession! How they puff off their cures and their wonderful remedies, and make a grand display of oft useless and injurious instruments! Again, is not the growing fashion of exhibiting before the patient experiments with urinary analysis apparatus, pulling out your urinometer, unfolding your test paper, holding up your test tube, &c., &c., often arrant humbug and consummate conceit? Such investigations should be made in private, or a professed chemist employed, (which is preferable,) for few men in large practice can give the necessary time for such manipulations. It is not creditable to make a foolish display and parade of one's skill at any time; and when that is done merely to astonish some enfeebled suffering fellow creature, or to pander to the morbid curiosity of over-anxious friends, it amounts to something worse than either vanity or egotism.

Such absurdities are equal to the vagaries of the great *anal* Hamilton, (as contradistinguished from vaginal Hamilton,) of Auld Reekie notoriety, who, as is well known, was in the habit of having the chamber-pots of his patients placed in order, and numbered, before he came with his wand to stir up, examine, and smell; and it is said, occasionally another of the senses was employed in this *poto*logical inquiry as well. But he (Dr. H.) was an original and talented man in his way, independent of his peculiar views; he struck out a path of his own, and could be trusted for his uprightness, which is more than can be said of too many degenerate members of our body at the present period. Another class of specials that oft abuse their profession, and deceive the public, are the spine doctors, with their extension boards, straps, springs, and machinery, muscles and ligaments being secondary agents to be relied on, and of little value, compared to artificial aids; the theory as well as the practice of too many of them being unstable and injudicious, though I admit it may be *profitable* in a pecuniary point of view. The use of the stethoscope has been, perhaps, as little abused as any modern invention connected with our art, though I have known and seen much foolish display in stethoscopic examination, and known it oft applied when it was as little required as a poke with a full-sized bougie, the prick of an exploring needle, the introduction of a trocar into an impregnated uterus, or the slipping a scalpel into an aneurism. But it is not, as in such cases as the above, or with instruments alone, that we see all this abuse; favourite theories and crotchets so possess and entrammel the minds of some of our faculty, that they seem oft to labour under a sort of monomania as regards disease. Broussais and his theory reign paramount with many, and every ailment is to be attributed to deranged state of the mucous membrane and affection of the stomach, and to dyspepsia. The liver and its secretions are ever at fault in the views of some. The kidneys and skin with others. And so on: this exclusive mode of reasoning is neither satisfactory or the treatment successful, and a fair, dispassionate, comprehensive view of disease and its symptoms, is apt to be disregarded. Another remark I venture to make, is, that as provincial medical men, we should try to keep, as a general rule, our patients out of the hands of such Londoners as I have alluded to if we have any respect either for the well-being of the persons, or of the pockets, of our patients.* It is not long since a patient of my own was brought to death's door by a fashionable physician, who erroneously treated an ailment of debility for an acute disease, and it was only the very opposite treatment to what he had adopted which restored my patient and saved her life. This I merely state to show that *fashion* does not always ensure success or satisfaction.

I will not, however, allow myself to proceed, or trouble your readers with any further remarks on this head, excepting in conclusion to express a wish—as I have a very confident expectation—that ere long the public mind will be sufficiently enlightened, to prefer in all cases, the straightforward, honourable, well educated and experienced practitioner to the charlatan and quack, whether in or out of the ranks of the profession. "Heaven," it is said, "helps those who help themselves," and we must set the example amongst ourselves of spurning every path but that of the open and straightforward one, and we must not hesitate to expose a class of men who degrade our noble profession. We must never rest satisfied till our ranks are freed from traitorous and unworthy members;—till mesmerists, hydropathists, homœopathists, and the like, or withdrawn from the list of qualified medical men, and the practice of our noble art is purified of such growing and glaring evils, as I have ventured thus imperfectly to call your attention and that of the readers of the *Journal.*

I have the honour to be, Sir,

Your obedient Servant,

J. INGHAM IKIN.

Leeds, March, 1851.

* I wish it to be clearly understood, that in saying this I only allude to the *abusers* of our art, not to the noble heads of the profession, or to the profession generally in London.

OBSERVATIONS

ON THE

SALE OF ARSENIC REGULATION BILL.

By JAMES TUNSTALL, M.D.,

Physician to the Eastern Dispensary of Bath.

Before I make any remarks upon the proposed enactment, I shall refer to the clauses of the Bill, which were three in number, and then proceed to show, that in its original form, it would have been quite inoperative for the purposes intended, viz., the prevention of accidents and offences by the use of arsenic.

"A Bill intituled an Act to Regulate the Sale of Arsenic.

"Whereas the unrestricted sale of arsenic facilitates the commission of crime: be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:

"I. That every person who shall sell any arsenic shall forthwith, and before the delivery of such arsenic to the purchaser, enter or cause to be entered in a fair and regular manner, in a book or books to be kept by such person for that purpose, a statement of such sale, with the quantity of arsenic so sold, and the purpose for which such arsenic is required or stated to be required, and the day of the month and year on which, and the name of the person to whom, such arsenic is sold, and the name of the town or other place, and also the name of the street and number of the house, if the same shall be said to be numbered, where such person shall abide, and whether such person or persons is or are a lodger in or the keeper of such house, by using the letter 'L' if a lodger, and the letter 'H' if a housekeeper, into all which circumstances the person selling such arsenic is hereby required and authorized to inquire of the purchaser before the delivery to such purchaser of the arsenic sold, and every such entry shall be signed by the person making the same.

"II. If any person shall sell any arsenic, save as authorized by this act, or shall, on any sale of arsenic, neglect to make the entries hereby required on such sale, or if any person purchasing any arsenic shall give false information to the person selling the same in relation to the particulars which such last-mentioned person is hereby authorized to inquire into of such purchaser, every person so offending shall for every such offence, upon a summary conviction for the same before two justices of the peace, be liable to a penalty not exceeding *twenty pounds*.

"III. Provided that this act shall not extend to the sale of arsenic when the same forms part of the ingredients of any medicine required to be made up or impounded according to the prescription of a legally qualified medical practitioner, or a member of the medical profession."

It is manifest that the first clause was intended solely to register the sale; it affords no protection whatever to the buyer on the one hand, or to the accidental misuse of the poison on the other, always providing that it had been purchased for a legitimate object. This omission has been supplied in the amended Bill, which requires the purchaser to be a male adult, who is also compelled to sign the book kept by the seller. The Bill appeared to me to be deficient in that it did not define who the persons should be, to whom the sale of arsenic should be entrusted; the correspondence which I last year undertook with the leading druggists of England, enabled the Arsenic Committee of the Association to report:—

"That the indiscriminate sale of arsenic and other poisonous drugs, by retail in a careless manner, is almost exclusively confined to those who sell drugs as an auxiliary to other little businesses, and who are ignorant of their doses, effects, and qualities, such as chandlers, grocers, hucksters, and general dealers, in thinly-peopled places, and in some instances in the low neighbourhoods of populous towns."*

The case which occurred a few days since at Chew Magna, in this county, where fourteen persons were nearly poisoned by arsenic sold by a baker's wife, by mistake for carbonate of soda, appeared to bear so strongly on this point, that I felt it my duty to send the account of it to the Earl of Carlisle, with a suggestion that the following should form the second clause in an amended Bill.

"*If any person otherwise than a member or licentiate of the Society of Apothecaries, or of the Pharmaceutical Society, or one accustomed to dispense medical prescriptions, as a part of his accustomed profession or trade, shall sell any arsenic by retail, such person shall, on proof of such sale before two Justices of the Peace, be liable to a penalty not exceeding £20.*"

And still further to carry out the views of the Association, I forwarded to Lord Carlisle a copy of my pamphlet upon this subject, a reprint of an article which appeared in the *Provincial Medical and Surgical Journal* of the 22nd August, 1849, and suggested the following clause for his consideration:—

"*That for every purpose, except for the arts and manufactures, and to the members of the medical profession, and then only to persons well known to the person selling the arsenic, no arsenic shall be sold by retail, unless mixed with powdered charcoal, or some coloured material easily recognised by sight, under the penalties hereinbefore recited.*"

His Lordship was pleased to reply in the following terms:—

"March 24, 1851.

"Sir,—I am much obliged to you for your considerate suggestions. I find the subject of licensing attended with greater difficulties than I can surmount, but I hope to give effect to the spirit at least of some of the remaining recommendations.

"I have the honour to be, Sir,

"Your very faithful servant,

"CARLISLE.

"To James Tunstall, Esq., M.D."

On the same evening the noble Lord, in moving the third reading of the Bill, "proposed that not only the seller should enter the name of the purchaser in a book, but that the purchaser should also enter his own name in the same book."

* *Provincial Journal*, April 3rd, 1850.

"It had been represented that cases of accidental poisoning had occurred, and it, therefore, had been suggested that arsenic should be coloured, that might interfere with its use in the arts, but not for its use in agriculture; he, therefore, proposed that no arsenic should be sold in quantities less than ten pounds, except in cases where it was to be used for the arts, unless it should be coloured with indigo or soot; and that no arsenic should be sold to any but a male adult person; and he should also propose that no arsenic in a less quantity than ten pounds should be sold, except in the presence of a person known to the seller." The Bill, as thus amended, was read a third time and passed.*

It will be seen that, with the exception of the clause restricting its sale to chemists, druggists, and apothecaries, the Bill now virtually embodies all the recommendations of the Committee of the Association. I must candidly confess that, with respect to this exception, I am disappointed. It has been shewn over and over again that the evil rests with the country general dealers. I regret that time has not been permitted me to communicate with the other members of the Arsenic Committee, for the Bill was ordered to be printed on the 10th, and passed the House on the 24th instant. I I think that the amended Bill will not reach the evils of the case, unless the sale of arsenic is restricted. On the other hand, however, it may be said that the introduction of the colouring matter will afford all the necessary protection; for it is not at all likely that country shops will order a greater quantity than ten pounds; and the difficulties thrown into the way of its sale by the registration clauses will no doubt tend materially to diminish the evil.

I think it of importance that its course should still be carefully watched through the House of Commons; for which purpose I have forwarded a copy of my pamphlet to each Member of Parliament, and have made arrangements to have a copy of the amended Bill forwarded to me as soon as printed; and would strongly urge upon every member of the Association the necessity of enforcing upon the Members of Parliament with whom they may be acquainted, the great importance of a restrictive clause, in order that the Act may be complete. It appears, indeed, perfectly absurd that in the middle of the nineteenth century arsenic and other poisons should be allowed to form a portion of the ordinary stock in trade of the village baker, grocer, and huckster, more especially when so favourable an opportunity occurs for abolishing so great an evil as the Bill now under consideration presents.

Bath, March 27, 1851.

* *Sun*, Tuesday, March 25, 1851.

Provincial Medical & Surgical Journal.

WEDNESDAY, APRIL 2, 1851.

On Saturday, the 9th of March, at the Worcester Lent Assizes, Emma Taylor was indicted for the wilful murder of her infant child. Mr. Hastings prosecuted; the prisoner was undefended. The facts of the case were as follows:—In the month of November last the prisoner was in the employ of Mr. Bullock, a farmer, near Pershore, as an in-door servant. On the 9th of that month Mrs. Bullock was in the garden at an early hour, and observed in some bushes under the prisoner's window, something which proved on examination to be the afterbirth of a child. She sent a charwoman who was then in the house, named Hannah Davis, to the prisoner's room, whom Davis found in bed, and in reply to several questions, confessed that she had been recently delivered, and that the child was in her box, of which she gave the key. On opening and examining the box, the body of a female child was found at the bottom, concealed under the prisoner's clothes. The prisoner stated that the child had fallen from her while she was standing by the side of the bed, that it never cried, and that she accordingly placed it in the box, and threw the afterbirth out of the window. Both Mr. Bullock and Hannah Davis deposed that they found marks round the neck of the child, some of which appeared like nail-marks, and others as if they had been caused by a tape or string; there was also a bruise under the ear. Mr. Graham Niven, a surgeon, practising at Pershore, examined on the same evening both the mother and the body of the child, and on the Wednesday following he made a *post-mortem* examination. Mr. Niven deposed as follows:—

I am a surgeon, residing at Pershore. I was sent for to Mr. Bullock's on Monday afternoon, the 9th of November last, and I there saw the body of a new-born female child. I also saw the prisoner; she had been recently delivered. The child had come to its full time; there were no marks of violence on its body, except round its neck. I found there several marks which appeared to me to have been caused by tying a piece of tape round the neck; they did not extend all round the neck, but were only seen on the anterior portion. They seemed to me to be of such a nature that they must have been inflicted during life; I do not think they could have been caused after death. Two days after I made a *post-mortem* examination. I examined the head and found a small coagulum of blood on the upper part of the head under the scalp; in other respects I found no traces of injury or disease; the brain was perfectly healthy. I examined the lungs, which were in a healthy state, and had been inflated with air; they floated in water; they had changed their colour, and assumed that which characterises them after respiration has taken place. I also examined the heart; the ductus arteriosus was slightly contracted, but pervious. In my opinion the child was born alive, but I would not undertake to swear positively that it was so. I believe that it was born alive, and that it did not die from

natural causes; from the marks on the neck death was in my opinion caused by strangulation. I do not think that those marks were caused by the prisoner's efforts at delivery; the nail-marks might, but the ligature-marks could not have been so produced. I do not believe that the child was killed by falling from the mother; I consider such an event to be possible, but highly improbable. In answer to a question from his Lordship, Mr. Niven said, that the ligature-marks could not have been caused by the navel-string during the birth, because there were distinct convolutions, which could only have been caused by tape.

Mr. Justice Patteson, in summing up the case to the jury said they were not to find the prisoner guilty, unless they were fully convinced, not only that the injuries were inflicted by her, but also that they had been so inflicted after the child had been completely born alive into the world; and he pointed out that the medical witness had not sworn positively to this point. He also dwelt strongly on an assertion made by the prisoner during the trial, that the medical man whom she had consulted at the Worcester Infirmary and elsewhere, had not informed her that she was pregnant, a statement which was apparently borne out by the fact that her master and mistress had been entirely ignorant of her condition.* His Lordship said that the test of floating the lungs had been proved to be fallacious, but did not allude to the circumstance of the change of colour, which only follows complete respiration; nor did he mention to the jury the last answer of the medical witness respecting the nature of the ligature-mark round the neck. The summing up was on the whole strongly in favour of the prisoner: and after a brief consultation the jury acquitted her of the murder, but found her guilty of the concealment of the birth. She was sentenced to one year's imprisonment with hard labour.

This case, like many others which are continually brought before the public, shows the impossibility of obtaining a conviction for infanticide, under the present state of the law, as laid down by the judges, and the necessity, in our apprehension, for some alteration therein. The difficulty primarily arises from the disproportion felt to exist between the crime and the punishment provided for it. The capital retribution which justly awaits a Rush and a Greenacre, becomes cruel severity when adjudged to a wretched woman, who, in the anguish, shame, and perturbation of her first delivery, when often perhaps a scarcely responsible being, lays violent hands on the child, for which in a few hours after, she might evince the fondest maternal affection. This consideration, probably, has led our judges to narrow down the evidence in these cases, and to exclude all testimony except a positive assertion of an actual fact, in a way which they never adopt in other criminal trials, and which makes a conviction, if the medical witness be candid, next to impossible. Directing the jury that the *complete* birth of the living child must be fully established—established, that is, by the positive assertion to that effect of the medical witness, the judges have affixed to these prosecutions a *sine quâ non* condition which can hardly be fulfilled. In the case before us, although no one single test of the child having been born alive can be considered infallible, their concurrent testimony—the fact of the child being full-timed, perfectly healthy, with lungs which had been fully inflated, and a ductus arteriosus slightly contracted, *with marks of violence sufficient to account for death*—furnished evidence which was really irresistible. Judged by the ordinary rules, Emma Taylor would have been convicted of murder, *and sentenced to death*. It is this terrible consequence which makes judge and jury alike anxious to shirk the responsibility of a verdict of guilty. Would it not be far better for the Legislature to interpose, and affix the punishment of transportation to the crime of murder of a new-born infant by its mother, with a special proviso that proof of the complete birth shall not be required? Such an enactment might have the effect of stopping a dreadful but too common crime, to repress which, the sentence of imprisonment at present (virtually) awarded, is utterly inadequate. Common sense, too, points this way: how can it be less homicidal to slay an infant three parts or half-born, than one which has had for a few moments an independent existence? We have only to add, that in the present instance all doubt is now at an end, by the full confession of the prisoner, which has, we are informed, been made; according to her own account, she laid the child on the bed after it had been born alive, and there strangled it.

* This assertion was entirely untrue: when an out-patient of the Worcester Infirmary, Emma Taylor had been told of her condition, and warned to make the necessary preparations.

We congratulate the members of our Association on the progress of the "Sale of Arsenic Bill" through the House of Commons. It is true, as Dr. Tunstall observes in his remarks, which

will be found at page 181, that there is no probability, unless strenuous efforts are made, that the sale will be restricted to chemists, druggists, and apothecaries, but still with that exception every other point has been gained. The importance of the restriction of the sale of arsenic is so great to the community at large, that we cannot sufficiently thank Dr. Toogood for his original suggestion, and Dr. Tunstall and the rest of the Committee, for their indefatigable exertions in carrying out so benevolent a design. It is not perhaps generally known, how strong has been the opposition to this measure on the part of the manufacturers and agriculturists. We should have thought that common humanity would have induced all those who use arsenic in any form, to guard its employment by every practicable means; but as, in all hazardous employments, the constant exposure to danger seems to dull the sensibility to its probable results, so in this case, those who ought to be most cautious, since they are continually offering temptation to the wicked, and freedom from punishment to the careless, have evinced the most reckless opposition to the enforcement of any restriction upon the sale. This is the only excuse which we can make for this otherwise unaccountable proceeding, but let the grounds for it be what they may, we have equally to thank the gentlemen who have superintended the progress of the measure, for their zeal and energy in its prosecution.

Reviews.

Address before the American Medical Association, at the Anniversary Meeting at Cincinnati, 1850. By John C. Warren M.D. Boston: 1850. pp. 65.

This is an address, in its objects very similar to those which are annually delivered in our own Association, and is intended to chronicle the recent improvements in the art and science of medicine. In the present case the retrospect does not embrace the whole range of medical science, but on the contrary, is limited to a few subjects connected with the branch of which the author is so worthy a representative—that of surgery. The subjects noticed are the microscope, lithotrity, tenotomy, the surgical use of cold water, and etherization. On each of these points the reader will find important information. There is one use of anæsthetic agents alluded to, which is certainly novel, as its propriety is likewise somewhat doubtful. Dr. Warren says:—

"The agony of death is a fair subject for the influence of ether. This supposed agony, in perhaps the greater number of cases, is a creature of the imagination. Nature, like a kind mother, has presented the phenomena of death with such accompaniments as she thinks necessary to deter us from resorting to it by our own act. . . . Some instances there are, in which there is real suffering. In these an invaluable friend is found in ether. And when the mortal strife is so far advanced as to leave neither hope nor chance of recovery, the duty of the physician is to interpose the means by which we may be quietly conducted through the final moment. This practice I adopted many years before ether was introduced; and I have followed it lately, though with great caution, and not without the clear knowledge and full assent of the patient and his friends." —p. 63.

Introductory Address on Medical Education. By Alexander Fleming, M.D., Professor of Materia Medica, Queen's College, Cork. 1850-51. Dublin: 1850. pp. 32.

A vast improvement is perceptible in the introductory lectures of the various medical schools since we were *in statu pupillari*. The last session in particular has been distinguished for addresses which, both in eloquence and moral tone, reflect a lustre upon the profession of medicine. In the former of these qualifications perhaps Dr. Fleming's lecture does not come up to some which have graced the metropolitan schools, but in the latter and more important, he need yield the palm to none.

In the outset Dr. Fleming warns his hearers that medicine is a difficult study. And he does well. Would that its difficulties, its responsibilities, and its requirements, social and moral, were more deeply impressed upon the multitudes of raw youths, who annually crowd the benches of the lecture room, some at least we trust would be deterred from pursuing a calling for which they are, by education and early habits, entirely unfitted; and a noble profession would less often be degraded in the eyes of the public.

The importance of a preliminary education equal to that required by other liberal professions, is strongly insisted upon by Dr. Fleming, as the chief means of giving to the medical practitioner that title to social consideration which is claimed by gentlemen in other walks of life. He also dwells forcibly on the necessity of the student giving an equal share of his attention to medicine and surgery, and not, as is too often done, to

allow himself to be attracted by the latter to the exclusion of the former. This is sound advice, and if it were more attended to in our medical schools, would save many an uncomfortable reflection in after life. After some further and equally excellent observations, on the necessity for cultivating a spirit of kindliness and forbearance towards those, who, in the eternal jostling of private practice, may sometimes appear as rivals, Dr. Fleming concludes with an explanation of the curriculum of study demanded at the Queen's College, Cork. This we think offers all that is desirable for the formation of enlightened medical practitioners—men, as he observes, "fitted to raise our social position, and advance our difficult science."

Foreign Department.

Epilepsy; Abscess of the Brain.—By M. Sissa.

M. Sissa, (*Encyclographie Médicale,*) relates the case of a man, aged 29, the subject of epileptic attacks of three weeks' date. The fit was preceded by tingling in the ears, and a pricking sensation along the cord, extending to the extremities. The first fit had occurred on the 18th of February, the second on the 20th of the same month, with increased violence. M. Sissa remarked a degree of wildness in his general attitude, and in the movement of the eyes of his patient; with this exception his intellectual faculties were intact. There was no acceleration of the pulse, or increased heat of skin. He complained of heaviness of the head, and likened it to having on a leaden cap.

A consideration of these symptoms led M. Sissa to form the diagnosis, that there was slow arachnitis of the cerebro-spinal system. He prescribed bleeding, (general and local,) mercurial frictions along the back, even to salivation, either alone or in combination with belladonna and aconitine. He also employed saline purgatives, and calomel and jalap. By these means he suspended the fits until the 30th of March; but on this day, the patient being a little fatigued, was again seized with convulsive fits. The same treatment was recommended, and a large blister applied to the nucha, afterwards kept open with mercurial ointment.

In about eight days the patient began to complain of headache, which, commencing on the right side, spread over the head; it continued during the day, and returned at the same hour on the following day. Subdued by the sulphate of quinine, it gave place to another pain, a little above the union of the right parietal bone with the occipital, which thence extended over the whole head, and did not again abate. The patient however ate, walked, and had no appearance of fever. In spite of bleeding, purgatives, and revulsives, things remained the same, until the 2nd of May, when the pain became all at once insupportable. The patient uttered continual cries, which neither fresh bleedings, nor the applications of ice could appease. Every moment increased the suffering; his arms were agitated with convulsive tremblings; still these alarming symptoms were unaccompanied by the slightest fever. All means proved useless, and on the 9th of May he died, without paralysis, without symptoms of apoplexy, and not having, for nearly forty days, shown any marked signs of epilepsy.

Post-mortem.—The skull was of extraordinary hardness, though not thicker than usual. After the removal of the osseous cap, the cerebral mass quickly escaped, as though it had been previously subjected to strong compression. The dura mater was nearly cartilaginous, with its sinuses empty, while the arachnoid and pia mater, on the contrary, were gorged with blood. The cortical substance of the brain was very thin, compared with the white substance. On detaching the brain a quantity of greenish pus escaped from the right posterior lobe. On continuing the examination a nearly round cavity was discovered in this lobe, large enough to contain a hen's egg, full of greenish pus, of the consistence of cream, and without smell. They estimated the quantity at about two ounces. The cavity was not covered with a cyst; it rather seemed that the cerebral fibres went out of the way to receive the purulent liquid. The other parts of the coats presented a rather marked state of softening, but it was not easy to decide whether it was connected with inflammation, or the effect of decomposition.

Abortive Treatment of Small-pox by Collodion.

When this fluid was first introduced to notice, we suggested in a communication which was copied into some of our cotemporaries, that it would prove valuable as an application to induce the abortion of the variolous pustule. We are therefore glad to observe, that in the hands of M. Aran, collodion has fully realized our anticipations.

In the *Bulletin de Therapeutique*, October 30th, M. Aran narrates the case of a youth who fell under his charge with confluent small-pox in an early stage. The face was thronged with pustules and was intensely swollen M. Aran applied a layer of collodian. In two days the lobes of the ears and lips, which had not been covered, exhibited fully-developed pustules, which, under the collodion the pustules were arrested. The application was several times repeated, and on the ninth day it peeled off together with the epidermis, leaving the skin of a rosy colour and without pits. On the ears were several deep cicatrices.

Muriate of Lime in Skin Diseases.

Chloride of calcium is not employed much in medicine, but according to Cazennave (*Bulletin de Therapeutique*, 1850) it is a valuable remedy in struma, and diseases depending upon it. He has used it in lupus, in chronic eczema, and impetigo, in doses varying from fifteen to thirty grains per diem, in some vegetable decoction or infusion.

Formation of Artificial Milk.—By Dr. PANUM.

We extract the following from the *London Jonrnal of Medicine* (March). In the July number of the *Bibliothek for Læger*, Dr. Panum writes as follows:—"It occurred to me that the question of the identity of the material I have been describing with casein, might be solved by the *synthetical* method, which, though it can seldom be satisfactorily employed in scientific diagnosis, yet in the inability of analytical chemistry with regard to the protein compounds, is not to be despised. If it were possible, by adding the necessary constituents, to form from the substance under consideration some universally known product containing casein, such as milk or cheese, we should have a striking proof of the identity of the substance with casein.

"I obtained a quantity of serum from bullock's blood. To this I added acetic acid, in the proportion of six drops of concentrated acid to an ounce of serum, and then a considerable quantity of water. The substance described in my former contributions sank on standing to the bottom of the vessel, so that the superabundant clear fluid could be poured off. On again adding water and letting the substance sink to the bottom, it was rendered almost perfectly free from soluble albumen, etc. After it had settled as much as possible, the water was poured off, so as not to waste the substance, which remained suspended in a greater quantity of water than casein is diluted with in milk. It was now my object to find out, whether the solution of this substance produced by salts or an alkali could be brought to coagulate by contact with the mucous membrane of the stomach of kittens or puppies; and whether it were possible to produce a substance which, in taste and other circumstances, should agree with milk. But as it would probably be difficult to make animals use the solution as milk, unless the other constituents of milk, namely butter and sugar, were mixed with it, and as the taste and peculiarities of cheese might be modified by them, I first tried by adding these substances, to produce a liquid which should have some resemblance to milk. At a temperature of 30 Reaumur, I added to the milky liquid phosphate of soda, till all the supposed casein was dissolved. I then added butter and sugar in the proportions in which they are usually contained in milk, and, after the butter was melted, I shook the whole mixture in a flask. The liquid at first greyish or dirty yellow, became of the colour of egg-flip, and as it cooled became more and more like milk. The clearer was the solution and the whiter the milk-like fluid. If the serum was perfectly free from blood-corpuscles, the emulsion, when diluted with water, had the same bluish colour as milk and water; but if there was a strong blood-red tinge in the serum, the solution in phosphate of soda had a reddish, and the emulsion a weak yellowish tint. The product had a taste which bore a most striking resemblance to that of true milk; only it was a little more sweet, and left a feeble, though recognisable, bitter after-taste.

[Not quite satisfied with this essay, Dr. Panum tries whether he cannot form a closer imitation. He says:—]

The most striking difference which the artificial milk presented on a superficial examination, was that it required a far shorter time than real milk to form a layer of cream on the surface, and that, after standing some time longer, a layer of clear liquid was formed at the bottom of the vessel. I ascribed this failure to the greater average size of the globules in the emulsion, as compared with true milk-globules. When I employed sugar of milk in place of common sugar, the emulsion was uniform, and showed no layer of clear liquid at the bottom of the vessel, even when more water was added. At the same time the average size of the corpuscles became less, so that they could not be distinguished by their size from the true milk-globules, and they were now free from any appearance of nuclei or granular cell-contents. The cream was longer in rising to the surface, and the great sweetness which the emulsion had when made with common sugar was no longer prominent, so that the liquid tasted still more like milk. A slight smack of salt disappeared when the butter was washed in water, and a slightly harsh taste of the butter was still farther removed when unsalted butter was used, which had been freshly churned and washed with water. There was still a slightly bitter after-taste, but this was removed by using carbonate instead of phosphate of soda, a much smaller quantity of the former salt being required to produce the required solution. It was now impossible for me to recognise, by the taste, any difference between artificial and real milk. As, however, it might be said that *de gustibus non est disputandum*, I submitted the liquid to the taste of others, with the same result.

[We commend our philosopher to the unscientific but perhaps more practical fabricators of milk, who are so numerous in the metropolis. If we are to believe Mr. Rudd, bullock's brains, treacle, and whitening, are amply sufficient to deceive the most refined London palate.]

General Retrospect.

ANATOMY AND PHYSIOLOGY.

Anatomy of the Urethra.—By Mr. HANCOCK.

Mr. Hancock, assisted by Mr. Hogg, has examined, microscopically, the structures surrounding the urethra. He found that the urethra itself was not muscular, but closely invested by organic muscular fibres continuous with the muscular coat of the bladder, which consisted of two layers, an internal and an external. The external passes forwards, and extends over the outside of the prostate gland; the internal, on the contrary, accompanies the mucous lining through the prostate, forming an involuntary muscular covering to the urethra in its passage through the gland. The membranous portion of the urethra is next closely invested by these muscular fibres, which cannot be mistaken for any portion of

Wilson's, Guthrie's or Sartorius' muscles, the latter being voluntary, and presenting the usual striated appearance under the microscope, whilst the former are involuntary and nucleated. Continued forwards, they reach the bulb, where they divide, the one part being continued onwards to the orifice of the urethra, lying between it and the corpus spongiosum, whilst the other passes on the outer surface of the corpus spongiosum, separating it from its fibrous investment, to which the fibres adhere pretty closely; these latter are also continued forward to the orifice of the urethra, and, in their course, invest the spongy portion of the bulb, urethra, and glans penis, entering very largely into the formation of that peculiar structure found at the orifice of the urethra, and which appears to consist almost entirely of involuntary muscle and elastic cellular tissue, forming an additional sphincter muscle to those usually described as met with in various parts of the body. It will thus be seen that the corpus spongiosum urethræ lies between two layers of involuntary muscle, the one separating it from the urethra, the other from its fibrous covering—an arrangement, doubtless, exerting considerable influence over the expulsion of the blood from the corpus spongiosum when erection of the organ is no longer required, as well as over the emission of urine and the seminal fluid.

PRACTICAL MEDICINE AND PATHOLOGY.

Beneficial Effects of Creasote in Diarrhœa.—By Mr. Kesteven.

The value of creosote in diarrhœa being little known, Mr. Kesteven places his experience of it on record; he does not, however, mention the forms of diarrhœa in which he has found it most applicable. The form in which he has administered it to adults has been as follows:—R. Creosoti, m. j. ad m. v.; Spir. Ammon. Arom., m. xv. ad dr. j.; Aquæ, oz. j. ad oz. iss.; where pain has been severe, Tinct. Camph. Co. has been added. He informs us that in no single case has creosote failed to be of signal benefit; in most cases one single dose has sufficed to arrest the course of the disease; in very few cases has it been requisite to administer more than the second dose. The remedy has been tried, (to keep within the limits,) it may be stated, in considerably more than a hundred instances, and its effects can therefore be confidently affirmed. Mr. Kesteven does not assert that equal success will always attend its use; the circumstances of local influences, epidemic constitution of the season, may, he admits, somewhat modify its effects in other hands. He explains the action of creosote in diarrhœa to its power of coagulating albumen and other animal principles.—*Medical Gazette*, Feb. 7, 1851.

Diagnosis of Fatty Degeneration of the Kidney.—By Dr. G. Johnson.

The urine in cases of fatty degeneration of the kidney has characters sufficiently destructive to render the diagnosis a matter of ease and certainty. It is commonly of a pale yellowish colour. When just passed it is clear, but after standing some hours it usually deposits a light cloudy settlement; sometimes in the early stages the urine has a dark smoky colour, from containing blood. The quantity secreted is less than normal, and its density in most cases exceeds the healthy standard. It is by no means unusual to find the specific gravity ranging from 1025 to 1030. The albumen is generally very abundant, so that when boiled the urine becomes almost solid. On a microscopic examination of the sediment, there may be seen transparent casts, of rather small size, in many of which oil globules are entangled; also cells containing oil globules in greater or less abundance. The majority of these cases have terminated fatally, while in a few instances the symptoms continue in a greater or less degree, the urine continuing highly albuminous, and presenting unequivocal microscopic evidences of the true nature of the disease. For the purposes of prognosis, it is important to distinguish between a case in which the urine presents the characters above described, and a case of simple desquamative nephritis, as it is to distinguish tubercular disease of the lung from acute pneumonia.—*London Journal of Medicine*, Feb., 1851.

SURGERY.

Treatment of Burns and Scalds with White Lead.—By Dr. Gross.

Dr. Gross states that during the last nine years he has paid much attention to the treatment of burns and scalds with carbonate of lead, in the form of white paint. It is extremely efficacious, and is applicable to accidents of every intensity. As the lead of the shops is too stiff for use, he mixes it with linseed oil, till it acquires the consistence of thick cream. With this the affected surface is thickly coated by means of a camel's-hair brush. If vesicles exist, their contents are evacuated with a fine needle, and the part well dried, otherwise the lead will not adhere. The dressing is completed by covering the paint with carded cotton, and a roller over all. In mild cases one application will be enough, in more severe ones several will be required.

Dr. Gross states that he has never seen any injurious effects from the white paint. In one case of extensive burn, the application was continued for five weeks. In short he considers the treatment perfectly safe in every kind of burn, and at every age. As a precaution against the toxic effects of the lead when feared, an occasional dose of sulphate of magnesia may be given. Dr. Gross considers that the white paint acts partly by excluding air, partly as a sedative. In many cases he says it acts like a charm.

Dr. Gross also speaks in favourable terms of collodion, but has not had extensive experience of it.—*Transactions of the American Medical Association*, Vol. 3.

General Remarks on the Diagnosis of Tumours of the Neck.—By Dr. Redfern.

This always presents great difficulties when the tumours are of large size, only slightly painful, and

fluctuate indistinctly. If a complete and accurate history of the case cannot be obtained, more than a general diagnosis may be unattainable, but when the precise position of the tumour at its commencement can be made out, when its relations to the larynx and trachea, and its mobility in regard to them and the surrounding parts can be ascertained, together with the rapidity and manner of its growth, there will be little difficulty in arriving at a satisfactory conclusion.

A tumour developed in the substance of the thyroid body presents itself in the front of the neck, is usually larger on one side than the other, is firmly connected with the larynx and trachea, moves freely with the larynx in deglutition, and when it is displaced laterally by manipulation. The other features vary with the nature of the tumour.

In ordinary bronchocele the swelling is soft, projecting, and elastic, without fluctuation, pain, or tenderness on pressure; it occurs in early life in the female sex, and in particular localities; it is simple in its nature throughout, and presents no tendency to degeneration of structure; it does not interfere with respiration or deglutition, nor does it affect the patient's health or comfort till it reaches a large size.

In cystic disease of the thyroid, the nature of the tumour becomes manifest sooner or later, by the presence of fluctuation in one or more cysts, by a glairy, serous, or sero-sanguineous fluid escaping upon puncture with a grooved needle, the fluid containing no cell formations, by the formation of the tumour taking place after the middle of life, by its slow and painless growth, and by the slight inconvenience caused by it, until it reaches a large size.

In cancerous disease of the thyroid, the tumour appears from forty to sixty-five years of age, is of great density, and generally painful; it is rapidly developed, and may attain a large size in a few months. It occasions great difficulty of breathing and deglutition from an early period, and the aspect and complexion indicate a malignant disease.

In medullary cancer the tumour is less uniform in its consistence.

Enchondromatous tumours are recognised by their density, slowness of growth, and absence of any sign of extension to surrounding tissues.—*Monthly Journal of Medical Science*, December, 1850.

MIDWIFERY.

Cæsarean Section.—By Dr. West.

In connection with an essay on the dangers attending the Cæsarean operation by M. Roubaix which appears in a former number, we give an abstract of a paper by Dr. West, in which he relates a case and also points out the peculiar sources of danger.

The subject of this history was a young woman, aged 27 (a patient of Mr. Wren, of Brownlow Street), whose health had always been indifferent, but whose person was not apparently deformed, and who reached the end of her first pregnancy without manifesting any symptoms especially calling attention to the state of her osseous system, with the exception of pains of a rheumatic character, and difficulty in walking, which last became very great during the last two months of her pregnancy. When labour came on, which it did at the end of the full period of utero-gestation, the existence of extreme pelvic deformity was at once ascertained by Mr. Wren, in whose opinion,—as well as in that of Dr. West, Dr. Murphy, and Dr. Ramsbotham,—the performance of the Cæsarean operation was indicated. It was accordingly performed by Mr. Skey fourteen hours after the commencement of labour, and eight hours after the rupture of the membranes; uterine action having, however, been feeble from the first, and having almost ceased since the escape of the liquor amnii.

The patient was, by her own desire, subjected to the influence of chloroform before the operation was begun: no difficulty was experienced in its performance; and a living female child was extracted. Very formidable hæmorrhage succeeded the removal of the placenta; and the subsequent contractions of the uterus were very tardy in their occurrence. The patient was left in a state of great exhaustion, from which she never completely rallied, and died in 108½ hours after the operation, apparently from the conjoint effect of the hæmorrhage during the operation, and of the shock to the nervous system. The treatment had consisted in the administration of stimulants and nourishment, both by the mouth and in enemata; and the patient was kept in the same manner almost throughout under the influence of opium.

The body, on examination after death, presented no evidences of serious inflammation; but the uterine wound was gaping widely, and even that of the abdominal walls was but partially closed. The pelvis presented in a most marked degree, all the characteristics of that deformity which is produced by mollities osseum; the pubic bones being projected into a beak 1·2 inches in length; the width of the pubic arch being reduced to 0·6 of an inch, and the distance between the tuberosities of the ischia to 1.2 of an inch.

The writer having noticed the high maternal mortality resulting from the Cæsarean section, and which he estimates at more than the number of 63 per. cent., at which the statistics of all cases recorded since 1750 places it,—since the results of cases occurring in hospitals abroad yield a maternal mortality of 79 per cent., and of cases in this country of 85·4 or 87·5 per cent., according to two different estimates,—proceeds next to point out the causes, apparently inevitable, of this high mortality.

These causes he refers to four heads: and illustrates their respective influence by reference to a table of 134 fatal cases in which the body was examined after death. The four heads are as follows:—

1st. The danger arising from hæmorrhage, which proceeds from a source different from that whence bleeding takes place in any other operation, and which is not capable of being arrested by the same means as suppress it under ordinary circumstances.

2nd. That dependent on the shock inflicted on the nervous system, as well by the violent interference with

the most important process that ever goes on in the organism within the same limited time, as by the injury to a part so important, and so richly supplied with nerves, as the uterus of a parturient woman.

3rd. The hazard inseparable from extensive injury to the peritoneum, when unblunted in its sympathies, and unaltered in its texture, as in cases of ovarian or other tumors, for the removal of which a similar exposure of the abdominal cavity is sometimes practised.

4th. That which results from the infliction of a wound on the uterus at a time when, in the ordinary course of things, the processes which nature is prepared to carry on in it consist in the disintegration and removal of its tissue—processes the very opposite to those essential to the repair of injury.

From a consideration of all these sources of danger, to the last of which attention has hitherto scarcely been directed, the author concludes that the rule which forbids the performance of this operation, when a reasonable prospect of delivery *per vias naturales* exists, is a good one.—*Medical Gazette*, Feb. 7, 1851.

TOXICOLOGY.

Fatal Poisoning from Bromine.—By Dr. Snell.

This case is considered by the narrator to be the only instance on record in which the poisonous effects of bromine have been witnessed in the human subject.

Dr. Snell was called to see Mr. ———, Tuesday morning, May 28, 1850, about half-past six o'clock. He was informed by the friends that half an hour previous the patient had swallowed bromine, with suicidal design. At this time the patient was complaining of incessant pain, which he described to be of a burning character; breathing slightly accelerated, short, and thoracic; pulse somewhat frequent, small, and quick; slight borborygmus and eructations from the stomach; several times during his illness partial tremors of his hands and arms were observed, but no decided convulsive movements were manifested, and the tremors were, doubtless, the result of excitement and fearful apprehension upon a naturally nervous temperament. An ounce bottle, with its tin case, was found upon the walk below his bedroom window, and he confessed having taken the whole, but a few drops spilled upon his hands and clothing in the act of swallowing. It was taken undiluted, directly from the mouth of the phial, hence the violent inflammation of the lips, tongue, mouth, œsophagus, &c. Another fact not to be omitted in the detail of the case is this, the poison was taken into an empty stomach; this circumstance alone, doubtless, caused a greater intensity, as well as an earlier commencement of the symptoms of gastritis. At the expiration of two hours and a half from the time the fatal dose was taken, the symptoms began to indicate some degree of prostration, surface cold and clammy, breathing short and laborious, with a prolonged expiration, attended with considerable mucous throat-rattle. The mucous secretion of the schneiderian membrane was copiously discharged, and saliva flowed very freely; pulse frequent, quick, and hard; no thirst, retching, or vomiting; pain more intense. In three hours and a half pulse more frequent and feeble; breathing thoracic, difficult, and slightly convulsive; mucous throat-rattle more extensive, and deglutition, which has been growing more and more difficult, is now found to be impracticable. The patient is becoming quite restless, throwing his hands and arms frequently into different positions. Cold perspiration breaks out, and the skin in many parts appears tinged slightly blue, and shrunk; countenance haggard, and blueish pale; features pinched; eyes sunken, pupils natural, conjunctiva has lost its lustre, and appears corrugated; no abatement of pain; frequent but ineffectual desire to stool; restlessness and other symptoms, indicative of extreme prostration and impending dissolution, increase rapidly. In four hours, pulse small, frequent, and almost imperceptible; no retching, vomiting, or thirst; patient is unable to protrude his tongue; cold perspiration increases; constant restlessness; pain moves lower down. Four hours and a half, no pulse; extremities cold; respiration decidedly convulsive, with the prolonged expiration peculiar to dying persons. The above symptoms continued to grow more intense till death relieved the sufferer, about seven hours and a half after the poison was taken.

Autopsy sixteen hours after death.—The head was not examined. Lower portion of the lungs congested, and a limited number of tubercles in the upper lobe of both sides. There was considerable serous effusion in the pericardium, but nothing more of particular importance was found respecting the viscera of the chest. The mucous surface of the œsophagus was not examined, but from the symptoms evinced during the illness of the subject, it is to be inferred that the mucous membrane of the entire œsophageal passage was in a state of high inflammation, and perhaps partial disorganization. The peritoneum was tinged reddish-yellow throughout the upper two-thirds, and highly injected in the parts lining the stomach, duodenuum, and liver. The lesser omentum, great omentum, and transverse meso-colon, were all deeply tinged with bromine, and injected to a considerable extent. On the anterior surface of the stomach, near the middle of the lesser curvature, is a large ecchymosed spot, two inches in diameter, the centre point of which is softened and gelatine-formed this may be owing to *post-mortem* changes. The whole anterior surface is very much injected, especially about the lesser curvature. On the posterior portion are several ecchymosed spots, surrounded by red borders. The internal surface was covered with a thick layer like tanned leather, and peeled off readily. The mucous membrane was softened, and intensely injected. The lower part of the stomach is hard and tanned. The same appearances extended to the duodenum.

The treatment pursued was experimental, and consisted of emetics, followed by starch, white of eggs, and ammonia.—*New York Journal of Medicine*, Sept.

UNIVERSITY OF CAMBRIDGE.

NATURAL SCIENCES TRIPOS.*

CAMBRIDGE, MARCH 8TH, 1851.

QUESTIONS.

Geology.—1. Define Geology, enumerate its leading objects, and determine its place among the Natural Sciences.—2. Among great mineral masses, what are the leading distinctions between stratified and unstratified rocks? Are we able to determine the probable epoch of any mineral mass by its internal structure? Quote examples, in point, both from aqueous and igneous deposits.—3. Enumerate some of the old "Sacred Theories" of the Earth. Explain, very shortly, what is meant by the Huttonian theory; point out how far it is inductive, and how far hypothetical.—4. Explain the natural mechanism by which aqueous vapour is elevated, then diffused through wide regions of the atmosphere, and afterwards precipitated. Explain the laws which govern the precipitation, and illustrate them by examples derived from the British Isles.—5. Explain the geopraphical conditions necessary to the formation of Glaciers. Enumerate their leading phenomena, the effects produced by them on the contiguous rocks, their progressive motion, and their transporting power. Explain the causes of their onward movement according to the views of De Saussure, Charpentier, Agassiz, and Forbes.—6. Shew, by the evidence of sections, that the earth has been brought into its present condition after repeated elevations of the land. What mechanical effects might be expected, from deep-seated forces of elevation, in the production and direction of great fissures? Do the valleys in any parts of England (*e. g.* in Cumberland and the Wealden country) illustrate a mechanical theory of elevation. How far does such a theory modify the Huttonian views on the excavating powers of rivers? How far can we determine the first epoch of a valley by geological data? How far can we approach to the past duration of the existing conditions of drainage, in any given valley, by the help of natural chronometers? Answer these questions by an appeal to well-known examples; or by actual sections.—7. What do we understand by modern alluvial deposits—diluvial drift—till—bowlder clay? Shortly give the theories by which the diluvial drift of England has been accounted for. Give the geographical distribution of the bowlders of Shap granite. Describe the modern alluvial deposits, the great brown clay, and the common flint-gravel of Cambridgeshire. What is the relative age of these three deposits? Determine the question by sections, and by a list of the imbedded fossils found in each.—8. Shew historically, by an appeal to known examples, the sympathetic action of many distant volcanic vents. State the conclusions Humboldt draws from facts of this class. Explain the terms basaltic lava, tractytic lava, obsidian, pearl-stone, pumice, amygdaloid.—9. Among geological deposits how do we distinguish plutonic or volcanic masses from the aqueous deposits with which they are associated. Illustrate the distinction by examples. Define Granite, Syenite, Porphyry, and Greenstone. How can we define the epoch of any mass of granitic rock? What are the relative ages of the granitic rocks of Mont Blanc, of Devonshire and Cornwall, of Charnwood Forest, and of Cumberland?—10. Enumerate the several minerals that commonly pass under the name of Feldspar. In what consists their specific difference? Define the mineral characters of Augite and Hornblende. Are they different species, or but modifications of one? Assuming their specific difference, how can we interpret the experiments by which one is made to pass into the other? Describe the experiments of Watt in illustration of the structure and formation of basalt.—11. Enumerate some of the most remarkable species of crystalline stratified rocks. In what sense is this structure to be called metamorphic? What explanations have been given of this structure? When considered on a great scale, do rocks of this class fall into any natural arrangement resembling that of Werner's primitive rocks?—12. What are the four great primary divisions of the Animal Kingdom, on the system of Cuvier, and on what tests is it founded? Enumerate the Classes of the Vertebrate Sub-kingdom, and enumerate the Orders of the several Classes, stating the distinctive characters of each.—13. Define the meaning of the terms Primary (or Palæozoic) Secondary, and Tertiary, as applied to fossiliferous strata. Enumerate the systems, or groups of deposits, into which primary, secondary, and tertiary rocks are now commonly subdivided: using the British types of comparison; and putting them, also, in co-ordination with good foreign types. Quote a few examples of the most characteristic fossils in the several systems, as well as in the subordinate groups—from the oldest to the newest. Prove the truth of the order of succession by an appeal to actual sections.—14. Shew that an arrangement of successive systems by the evidence of natural groups is very nearly coincident with an arrangement on fossil evidence. Point out some cases where the arrangement of natural groups has been modified, during the progress of geology, by the application of palæontological evidence.—15. Explain the meaning of the word *Trias*. Are the groups of strata defined by this word well represented in Britain?—16. Explain the classifications of Fishes given by Agassiz. Enumerate some of the most famous palæozoic species, and describe their peculiarities in contrast with modern Fishes. What is their rank on the general organic scale?—17. Enumerate the Reptile Orders, on the system of Owen. Describe the anatomical peculiarities of the Enaliosaurs and Dinosaurs. Taken collectively, what is the rank of the secondary Reptiles, when compared with the Reptiles of the tertiary and modern periods?—18. Explain the terms Eocene, Miocene, Pliocene. In which of these subdivisions do we now group the several tertiary deposits of England?—19. In what subdivision can we place the raised beaches on the coasts of Devon and Cornwall, and similar deposits on the Western coasts of Scotland?—20. Explain the anatomical reasons that have led geologists to refer certain fragments of small jaws (found in the lower Oolites of Stonesfield) to Mammal genera.—21. State the arguments for and against the following inference, viz., that in the oldest palæozoic strata we have not only reached the oldest known traces of organic life, but the oldest terrestrial monuments of organic creation.—22. Reviewing the whole fossil evidence, shew that it does not lead to a theory of natural development through a natural transmutation of species.

GENERAL PAPER.

I.—*Chemistry.*—1. State the laws according to which chemical combination always takes place. What is the relation between the equivalent weight, the equivalent volume, and the specific gravity of a gas? The equivalent volumes of oxygen, hydrogen, and nitrogen are as 1 : 2 : 2 : and their specific gravities are 1·103, ·069, and ·973; find the equivalent weights of oxygen and nitrogen, that of hydrogen being unity.—2. Enumerate and describe the compounds of sulphur and oxygen, giving the chemical formulæ for each compound. Describe and explain the process for forming sulphuric acid by the combustion of sulphur and nitrate of potassa or soda.—3. What different classes of compounds are included under the general name of *salts?* What is the nature of the compounds termed by BERZELIUS *sulphur-salts?* What are the general characteristics of the nitrates?—4. State the chief points of distinction between

* Concluded from page 167.

organic and inorganic compounds. What are organic bases? Define *isomerism*, and give instances of it.—5. Describe the chemical changes which occur, and the other phenomena observed, when a solution of sugar is submitted to the action of *ferment*.

II.—*Mineralogy.*—1. All mineralogical arrangements must be, in effect, chemical. Give an account of the first and second chemical systems of BERZELIUS. Point out the superiority of the latter over the former, and the objections to which the latter is still exposed.—2. Does *pentagonal* symmetry ever exist among crystals?—3. Define a *zone*, and shew how to determine by observation all the faces that belong to a given zone.—4. State the systems of crystallization and chemical formulæ of *rutile*, *brookite*, *anatase*, and *oxide of tin*. Are any of these minerals isomorphous? In what geological formations do they usually occur?—5. To what system do the crystals of $CaO + SO^3$ belong? State the number and direction of the principle cleavages. Are the crystals isomorphous with those of $BaO + SO^3$? Compute the quantities of lime, sulphuric acid, and water contained in 100 parts of $CaO + SO^3 + 2HO$; having given $O = 100$, $H = 12{\cdot}48$, $Ca = 251{\cdot}5$, $S = 200{\cdot}75$. To what system do the crystals of this substance belong? In what direction or directions do they cleave most readily? Is it isomorphous with any other chrystallized substance? What is its hardness in the scale of MOHS? Shew how the presence of lime, sulphuric acid, and water may be detected in it.

III.—*Botany.*—1. Describe the appearance of transverse sections of the stems of exogenous trees, endogenous trees, and tree ferns. Explain the peculiarities of growth to which the differences are owing.—2. In what parts of a plant does assimilation take place? What are the principle chemical changes involved in this process?—3. State the opinions most worthy our attention on the structure and composition of starch granule.—4. In what natural orders do we find the whole structure of the plant composed of cellular tissue? Describe the general characters of the organs of reproduction in these orders. 5.—Describe the general structure of Pollen, and the phenomena observed at the period of impregnation.

IV.—*Anatomy and Physiology.*—1. Describe the appearance of human blood as seen under the microscope. What are the organic constituents of the solid and fluid portions respectively? What chemical elements are contained in each of these organic constituents? Describe the phenomena which are observed on the removal of the blood from the living body.—2. Give a general account of the chemical changes which take place in the blood in the course of its circulation through the body, and in its passage through the lungs and through the kidneys.—3. In what respects do the structure of the heart and the course of the circulation of the blood in reptiles, fishes, and crustaceans differ from those in mammals?—4. How far is the action of the heart dependent on the nervous system? Will the mechanical action of the heart account for all the phenomena of the circulation?—What are the peculiarities in the structure of the teeth and jaws of Rodents?—6. Describe the compound stomach in ruminants, its structure, and the mechanism of rumination. Give remarkable instances in vegetable feeders in which the complexity of the stomach varies inversely as that of the cæcum.—7. How do you account for the contraction and dilatation of the pupil of the eye?—What are meant by fissiparous, gemmipparous, oviparous, and viviparous reproduction? In what classes or orders of animals do we find these modes of reproduction respectively to prevail? Describe the mode of reproduction of the aphis. What explanation has been given of this and similar phenomena?

V.—*Geology.*—1. Define geology, and distinguish it from palæontology and physical geography.—2. What results have been arrived at experimentally respecting the internal temperature of the earth? How do these results bear upon the metamorphic structure of certain rocks? Has any theory been proposed for the continuance of metamorphic action during successive geological periods of the earth?—State the evidence in proof of the elevation of strata at successive periods. Give some modern examples of this process.—Give a brief outline of Darwin's theory of the formation of coral reefs, and his classification of them.—Enumerate and briefly define the divisions, systems, and groups into which stratified deposits have been separated. By what observations, and on what principles have their relative ages been determined?

Correspondence.

THE BENEVOLENT FUND.

To the Editor of the Provincial Medical and Surgical Journal.

MR. EDITOR,—Will you pardon me for begging a space in your valuable journal, for the advocacy of the Benevolent Fund, which may fairly be asserted to be *one great object* of my existence. It was said of one of old, who was pleading his own cause, with the sincerity and earnestness of honest conviction,—"Paul, thou art beside thyself; much learning doth make the mad." But his reply was,—"I am not mad most noble Festus, but speak forth the words of truth and soberness" So, I doubt not, there are many amongst my brethren, who set me down as a *maniac*, and who pity me as demented. I know full well that it is the common indication of insanity, that the patient thinks all the world mad, while he alone, in the solitary grandeur of his exclusiveness, is the only rational person; and therefore, this is no proof that I am not entitled to the sympathy and compassion of your readers, because I have been reft of my *reason*—that great prerogative and attribute of mind.

But if I shall succeed in proving that my own conduct is founded upon undoubted and acknowledged principles, and that I am not exclusive in my attachment to this "one great object of my life," I shall by such means have established my claim to sanity;—shall have shown the correctness of my judgment;—shall have proved the consistency of my conduct;—and shall have established my title to be listened to attentively, while, in the words of the great orator before alluded to, I may be permitted to say to each one of my readers,—"I would to God, that not only thou, but also all who hear (read) me, were both almost and altogether such as I am," *except*, indeed, those imperfections which attach to humanity. And if I shall succeed in establishing my premises, I shall be entitled to make an appeal to the reason and conscience—to the principle and feeling of all my readers, who may not have contributed to the support of the Benevolent Fund, or who may not now be subscribers to that fund.

I shall set out with the assertion, that the Benevolent Fund demands the support of every member of the profession; and I propose to establish this assertion by a reference to two principles—first, *secular*; and secondly, *moral or religious*.

I. *Secular.*—We are all members of a vast Association, one of whose fundamental objects is "the maintenance of the honour and respectability of the profession generally in the provinces, by promoting friendly intercourse and free communication of its members, and by establishing among them the harmony and good feeling which ought ever to characterize a liberal profession."

But let me ask, how can this principle be carried out, if we turn our back upon our unfortunate brethren;—if we superciliously pass by the brother who is disabled by paralysis,—who is distracted by temporary embarrassment,—who has fallen a victim to unavoidable misfortune? How can it be carried out if we turn a deaf ear to the voice of sorrow and of sickness,—if we refuse to listen to the wailing of the bereaved widow, or to the cry of the helpless and starving orphans? How can it be carried out, if we will not lend a helping hand to restore the honour and respectability of him who has been unable to meet his creditors,—who has himself perhaps been the unfortunate inmate of a prison? How can it be carried out if, in the desolation of our selfishness, we withhold those self-denying sacrifices to maintain that "harmony and good feeling," which must ever depend upon the reciprocal interchange, not only of good wishes, and kind words, but also of veritable self-denying acts of benevolence? In a secular point of view, therefore, we are bound to contribute to the support of the Benevolent Fund, which for the last fifteen years has been intimately *incorporated with our Association.*

II.—But my second principle has a moral or religious basis. It is a Christian's duty to alleviate the wretchedness of destitution. "Whoso hath this world's good, and seeth his brother have need, and shutteth up his compassion from him, how dwelleth the love of God in him?" It is thus made a test of our common Christianity. It is true, that this principle may be attempted to be evaded, by saying, that we possess not "*this world's good,*" and therefore cannot give. Now this question must be tried on Christian principles: and here it is clear that the *widow's mite* has been declared to be more than the gifts of all those who had cast into the treasury of their abundance,—and it is equally clear, therefore, that the actual motive-principle of charity, is *self-denial.* It is not the giving of that which costs us nothing, but of that, to spare which, has required the abandonment of some little luxury, or comfort, or convenience, which we had previously enjoyed—and lawfully enjoyed. And seeing that, as *individuals,* we cannot often meet with these cases in private life, it becomes our paramount duty to contribute to the support of a fund which is set apart for this purpose—which is always ready to listen to, and investigate the applications of the wretched—and to extend its aid to the deserving in the proportion in which your liberality, or the contrary principle, may enable them to do.

Thus, then, I have established my second principle and proved my title to sanity—that I am not *exclusive.* Placed in a prominent and responsible situation by the kindness and good opinion of my brethren, it is necessary for me to give a preference to the fund, whose especial care is devolved upon my attention; and I have conscientiously and uniformly striven to redeem my pledge given three years since, that I would exert my best energies for the advancement of its interests; and that I would neither rest myself, nor let others rest, till I had seen the establishment and enlargement of its resources, commensurate with the profession it represents, and with the mass of misery which it professes to relieve. Facts, however, will prove that my support is not confined to this institution,—but that it is extended to others which are local in their operation —and *provident* in principle—or which are, in fact, pursuing the same object, though by somewhat different routes.

Having thus established my claim to be heard as a rational man, I come now to the application of these principles. And first, what is the fact with regard to support from members of the Association? It is simply this, that reckoning all the contributors to the Benevolent Fund, both *donors* as well as *subscribers,* from among the members of the Association—and we have just *one* such contributor for every four-and-a-half members—not, therefore, one *fourth, or nearly so, are regular subscribers to their own incorporated Benevolent Fund!*

Now, Mr. Editor, this surely ought not to be, and as a proof that it ought not to be, I will give you a sketch of some of the cases relieved since last July. In the eight months which have passed, we have relieved twelve medical men, in various forms of difficulty, chiefly induced by sickness or other infirmity; we have granted annuities to one aged medical man, and to three widows; we have aided two medical men who have been disabled by paralysis; we have extended our help to eleven widows and families of medical men, all left in deplorably-destitute circumstances, and one of whom was deprived of all her earthly support, and left with a large family, in a single instant, by the suicide of her husband, whose brain had been overturned by accumulated difficulties; we have rescued one medical man, with a large family, from utter destitution, and have placed him in such a position as enables him to support both himself and them; we have aided in the outfit for emigration of two female orphans of medical men; we have contributed to smooth the dying pillow of two who have gone before us to their long home; we have contributed to the well-being of two somewhat aged orphans of medical and literary men who were now placed in great difficulties; and we have assisted in the education of three other orphans, besides various other forms of misery which have come before us, and which need not now be particularized. And we have been *unable* to preserve one family from parochial relief; or to prevent other forms of hopeless degradation, in which a son of a medical man is at work in a coal mine, and three daughters are variously employed in menial domestic offices, for salaries not exceeding ten pounds a year.

And is there, Mr. Editor, a single heart which is not moved by this recital? Is there a solitary individual whose judgment remains unconvinced as to the necessity of relieving these forms of wretchedness,—or, I may add, of *himself being a party to such relief?* Is there a heart so hard that it cannot feel for other's woe, and that it does not beat responsive to this appeal, and come forward in aid of the misery of his brother? Among the individuals whom I am just now addressing, is there one who can willingly turn a deaf ear to the lament of the widow, or to the feeble piteous cry of helpless in-

fancy, pinched by want, to which God grant they and theirs may be utter strangers? Is there one who could pass by in cold indifference the recital of such destitution? Yea! is there one who could by so doing willingly plant a thorn in the bosom of one sufferer, and add a sting to the sorrow, by which the brain is already overwhelmed—even the sting of withholding his active sympathy, and thus declaring that such sorrow was not appreciated by the wealthy and the prosperous, or that its victims did not belong to the same family with ourselves?

Yet it is an astounding fact, that not one in five of the members of our great Association is a *subscriber* to the Benevolent Fund,—not one in five who would spare even five shillings a year to save a wretched brother or his starving family from parochial relief. It is an *astounding fact*, and I mention it as such, because it is hardly conceivable that a penny a week could not be spared for such an object; not that I advocate so small a sum as a subscription: it is too small, too inexpressive of the feelings of a gentleman towards his brother or his sister in distress, as if *their misery* could be put upon a level with the ordinary street beggar; but even this small pittance is withheld, and if given by each, even this would realize a considerable sum, and enable the Committee to act with confidence, instead of now being almost always indebted to the kindness of their Treasurer for advancing sums which are imperatively called for, for the relief of misery, which will be heard, and *must be relieved*. And yet there must be an end even to these advances, and unless the Committee be adequately supported by their fellow-associates, they must eventually be compelled to withhold their relief from cases of the deepest distress and destitution. And shall it ever be said, to the disgrace of our noble profession, that we are liberal to others, but not so to ourselves;—that we are charitable to all but our own brotherhood;—that we are bountiful to all but to those who have the largest claim upon our resources? And thus shall our motives of ordinary charity be left open to the suspicion of being grounded on that which is sinister and selfish,—and of being given with a provident eye to the future harvest which might be reaped from the seed thus sown?

There may, however, be those who will reply, that they are already contributors to benevolent funds for the same objects; but this is impossible, for there is no other fund in *this country, aut simile aut secundum*. In a paper which I have recently inserted in the *Medical Times*, I have shewn the distinction between our fund, which is *purely charitable*, and all the other medical relief funds which are pseudonymously called *benevolent*. Doubtless they are *benevolent* in the restricted sense of *friendly*, in which sense all the members of every mutual provident fund are benevolent; they take care of themselves and others also. But they are not *benevolent* in the sense in which I now employ the term—as contributing for the relief of the wretchedness of others, hoping for nothing in return; unrestricted to membership, unconfined to a specific locality, but extending its aid to sorrow in every shape, and to suffering in every place.

It may be said by others, that they possess not *the means* of subscription. Now, feeling as I do, the circumstances of the present times, and how grievously they press upon professional incomes; how much those incomes are diminished, directly and indirectly, by the depression of agriculture, by the various forms of quackery, and by none worse than by individuals thinking they can prescribe for themselves; and by the various and unscrupulous frauds and trickery by which the medical man is cheated out of his just remuneration; and appreciating the enlarged expenditure which is rendered necessary by the education of the day, I am fully disposed to make every allowance for this reason. But there can be very few instances among our associates in which it can be more than one of the arts of evading a charitable subscription. When the income is narrow, but not so narrow as to preclude a subscription to the Association for our own benefit, a very little self-denial will enable each one to *do something*, and express his good will, in so just, and good, and holy a cause. And among those who seem not to possess *the means* for this additional call upon their pockets, is there no plan to be devised for contracting the expenditure, so as to secure the necessary dole of charity? Is there no luxury that can be lopped off in order to supply this sum? Is there no expense that can be spared? The very act of *self-denial* in order to effect this object, will create such an amount of *self-respect*, as in itself to more than compensate any supposed loss. There are those who have *not* the means, and yet will be found, themselves and families, at balls, races, dinners, various parties of pleasure, and subscribers to various amusements—all very proper in themselves perhaps, but highly detrimental to the tone of high-minded feeling, if indulged in at the expense of one sorrow unalleviated,—of one tear unassuaged,—of one sigh unattended to,—of one plaint unheeded,—of one misery unrelieved. And this is to be carried out upon principle, not simply when the feelings are excited by the knowledge of a case of wretchedness in our own neighbourhood, but by the knowledge of the fact that such cases do often occur, that they are presented to the Committee of the Benevolent Fund in such numbers, and with such fearful aggravations, as to be beyond their powers of adequate relief. Oh! then, give them those powers! withhold not your aid from this Godlike charity; withdraw not your support, but contribute to the relief of unspeakable sorrow in him who is bowed down by affliction—

> "And many a furrow in whose grief-worn cheek,
> Has proved the channel for a flood of tears."

And now, Mr. Editor, let me, in conclusion, appeal to each one of my readers—to each one of my associates. What have you done to aid this Godlike institution in its labours of love—labours which approximate man more nearer to his Maker than any other sublunary act? Are you a subscriber to the Benevolent Fund? Your means are shown by your subscription to the Association: this is for your own benefit and advantage. But are you also a subscriber for the benefit of others? Can you lie down upon your pillow this night with the comfortable reflection that you have done what you *could* for the relief of the sufferings of your brethren? Can you repeat the prayer for daily bread?—or that it may please "Thee to have mercy upon all men," if you have not shown mercy to the helpless, the destitute,

and hopeless sufferer? Oh! if you are not already a subscriber to the utmost of your power, let me entreat you, as you value your peace of mind here—the estimate of your present character and your future happiness, to lose not a day in inscribing your name as a subscriber, to the utmost extent of your resources. Let him that hath much give of his abundance; let him that hath little give of that little; remembering those of whom it was said, that the *riches* of their liberality abounded out of their *deep poverty;* and remembering also, that it is *accepted* according to that a *man hath*, and not according to *that he hath not*.

It has always appeared to me that an after-dinner collection at each one of our general and branch Anniversaries was a peculiarly grateful method of adding to the funds of our institution; and that when the heart was warmed and softened by the hilarities of genial and fraternal intercourse, the festivities of the day and the toast of the Benevolent Fund would be *sanctified*, and stamped with ineffable truth, if supported by a small contribution, to those who know no festive day, and who actually know not where to look for to-morrow's sustenance for themselves and their families. But *quot homines tot sententiæ*. There are, I find, many who strangely think that the zephyr of charity is calculated to disturb the Favonian breeze of the "feast of reason and the flow of soul;" and although, as an individual, I cannot enter into such views, I cheerfully yield my own to the general harmony of our convivial meetings. Far be it from me to insist upon any *peculiar method* of enlarging our funds: here I cheerfully give way to the expression of general feeling. But I cannot equally give way on the general subject, or yield this principle,—that it is a duty, a privilege, and a pleasure to contribute to the relief of the afflicted and the destitute. And if each associate will fulfil this duty, and reap this privilege, and enjoy this pleasure, the funds would not require the aid of an *after-dinner collection*. Laymen look on and wonder at our apathy, and hesitate to help them who will not help themselves. O! let this plague spot in our history be blotted out by the tear of sympathy, and dried by the outstretched hand of unfettered charity.

In the paper in the *Medical Times* of last Saturday, to which I have already referred, I have mentioned two other methods of charitable donation; the first to consist in the handing over to the Benevolent Fund all the fees received from Life Insurance Offices; the second, in the donation of old clothes—a species of charity which, though managed unostentatiously, and unobserved by the Treasurer or his family, has been found of infinite service in enabling the child of misfortune to assume an appearance which has fitted him for a situation, and given him the garb of a gentleman; and also been most useful to persons emigrating. I can only add, that I shall be most happy to receive the above-mentioned supplies; and that donations of old clothes for gentlemen, ladies, or children, will be thankfully applied to this sacred object.

Donations and subsbriptions are earnestly solicited, and may be paid to the Treasurer, Mr. Newnham, Farnham, by post-office order or cheque; or to Messrs. Herries, Farquhar, and Co., Bankers, London.

WILLIAM NEWNHAM.

Farnham, March 10, 1851.

CRITICAL REMARKS ON MR. SKEY'S ACCOUNT OF THE PERITONEAL COVERING OF THE DISTENDED BLADDER.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—In your review of Mr. Skey's new work upon "Operative Surgery," published in the last number of the *Provincial Medical and Surgical Journal*, no notice is taken of an extraordinary statement which he makes whilst speaking of the operation of puncturing the bladder above the os pubis, and I shall therefore feel obliged if you will insert this letter to call the attention of surgeons to the subject, for it is a matter of importance that students and practitioners should not be misled in a practical question of this kind.

Mr. Skey states* that the peritoneum is perforated twice by the trocar in the performance of this operation. He brings forward to support his views, neither facts nor actual experience, but considers it unlikely that nature would deprive the bladder, during the state of distention, of one of its most extensible coats.

The membrane in question will doubtless stretch to a certain degree; but Mr. Skey could never have supposed that it was sufficiently elastic and extensible to cover a bladder when collapsed in the pelvis, and then without shifting its position, or gliding upon the muscular coat or the muscles of the abdomen, to cover the same organ as completely when distended up to the umbilicus.

In hernia, the case to which Mr. Skey alludes in support of his hypothesis, there can be no doubt that, when a rupture is suddenly produced, the peritoneum slips out from its place in the abdomen, and does not merely give way by its extensibility and elasticity before the protruded viscus. Mr. Laurence, in his "Treatise upon Ruptures,"† describes the connecting medium of the peritoneum to the subjacent parts in the lower and anterior part of the abdomen, as being "a soft, extensible, and elastic cellular substance, which yields readily when the membrane is subjected to the action of a distending force, and thus allows it to undergo a real change of situation or displacement, without any laceration of the connecting medium."

In pregnancy the peritoneum of course stretches to allow of the increase in the size of the uterus, but the broad ligaments and other neighbouring folds are also made use of to cover the distended organ, and become obliterated and lost. This fact, if Mr. Skey will admit the use of an argument drawn from "obstetricy," proves that the peritoneum is capable of a change in its position with relation to the viscera in the abdomen.

It will also strengthen the conviction of those who hold the common opinion on this subject, to know that Sir Astley Cooper, Mr. S. Cooper, Fergusson, Druitt, Chelius, Cruvelhier, and others, speak of the little chance of the peritoneum being wounded in these cases from its being raised out of the way by the distended bladder. Mr. S. Cooper, in a note,‡ alludes to a preparation in the Museum of London University, exhibiting the track of the trocar, which "proves that

* Operative Surgery, p. 515—516.

† Laurence on Ruptures, p. 16.

‡ Cooper's 1st Series, p. 684. Sixth edition.

Mr. King's statement of the peritoneum being necessarily pierced twice by the trocar before the bladder is reached is a mistake."

About three weeks ago a patient died under my care at the Bristol Royal Infirmary, from sloughing of the nates. He was transferred to me from a medical ward, to which he had been admitted for disease of the spine, and, as it turned out upon the *post-mortem* examination, with suppuration within the theca vertebralis. For the last thirty-six hours of his life he had retention of urine, and the catheter was passed for him, but when he died his bladder had not been relieved of its contents for twelve hours.

At the *post-mortem* examination, (besides many other appearances,) the bladder was seen to reach nearly up to the umbilicus, and the peritoneum was reflected *directly* across from the fundus of the bladder to the posterior surface of the abdominal muscles, leaving *at least four inches above the pubes*, where the muscular coat of the bladder was lying against the abdominal muscles.

The state was so obvious and well marked that I drew the attention of the students present to the position of parts, and pointed out that in such a case the bladder could be easily reached by a trocar, without any probability, or scarcely possibility, of wounding the peritoneal cavity.

A statement upon an anatomical point of this kind coming from an Assistant-Surgeon to St. Bartholomew's, and a Lecturer on Surgical Anatomy, ought to be well considered, and every opportunity taken of settling it by an appeal to facts, and if this is done I have little doubt but that the result will prove that Mr. Skey is mistaken in his opinion.

I remain, Sir,

Your obedient servant,

AUGUSTIN PRICHARD,

Surgeon to the Bristol Royal Infirmary, and Lecturer on Anatomy and Surgery at the Bristol Medical School.

Red Lodge, Bristol, March 25, 1851.

[The above opinion of Mr. Skey's entirely escaped our notice, or we should certainly have taken the same view as that held by Mr. Prichard.—Ed. J.]

ON THE STYPTIC POWERS OF MATICO IN UTERINE HÆMORRHAGE.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—Having lately witnessed very satisfactory results from the application of matico in a case of hæmorrhage from the uterus, I think it my duty, through the medium of the *Journal*, to lay the case before my professional brethren. The age of the patient is 37 years, she has had ten children, the youngest being 16 months old; during the seventh month of her last pregnancy she felt darting pains in the lower part of the womb, which she had experienced, more or less, up to the present time. Since the birth of her last child, she has had no regular menstruation, but has been the subject of hæmorrhage from the womb at uncertain intervals; she has also lately perceived a slight enlargement of one of the inguinal glands.

On examination, the os uteri was found to be irregular, having an ulcerated surface, with hard edges, occupying one-third of its circumference. In spite of the recumbent posture, and the injection of a strong solution of nitrate of silver three times a day, several napkins continued to be soaked with blood during the night and day for ten or fourteen days, and the patient began to evince the usual symptoms of chronic hæmorrhage. I then made a paste of matico leaves, mixed with a little mucilage of acacia, and having rolled it into balls of a convenient size, three or four of them were introduced into the vagina, and kept in contact with the os uteri by a firm plug of lint, completely filling up the vagina. No pain or inconvenience from this application were experienced, and the bleeding ceased entirely, and it was not renewed after the plug and matico came away at the end of ten days. Although the os uteri continues much in the same state, and there is too much reason to fear that malignant disease exists, yet the effect of the application of matico in this case increases my confidence in its styptic power, and has made me determine on using it, in this same form of paste, in the troublesome hæmorrhage which occurs from carcinomatous and other unmanageable ulcerative surfaces; I shall also try it in leucorrhœa accompanied with tendency to prolapsus uteri, cases which often defy injections of decoction of pomegranate rind, and other astringent applications.

My attention was first directed to the styptic power of matico a few years ago, by Mr. Hoare, a practitioner in this town, who had found a strong infusion of it surpass all other means, as an injection, in cases of bleeding from internal hæmorrhoids. My own subsequent experience of it in similar cases, has fully borne out his good opinion of it, and in one instance, viz., that of a lady whose health was failing from repeated loss of blood from the rectum, there has been no return of hæmorrhage since the use of an injection of infusion of matico, two drachms to a pint of water, and some considerable length of time has now elapsed.

I am, Sir,

Yours very faithfully,

FREDERICK FRANCIS GIRAUD.

Faversham, March 14, 1851.

Medical Intelligence.

PROSECUTION UNDER THE LUNACY ACT.

At the Kent assizes, held last week, at Maidstone, Dr. A. B. Maddock and Mr. Perfect, the proprietor and medical officer of the lunatic Asylum at Malling, pleaded guilty to an indictment preferred against them by the Commissioners of Lunacy for making false entries in their books, representing that no personal restraint had, during a certain period, been used towards any of their patients. Dr. Maddock also pleaded guilty to a second indictment. The defendants pleaded guilty, as they stated, to spare the exposure of the names of their patients. The case, however, was gone into, and the indictment fully sustained. Mr. Baron Parke said the question was not whether restraint was necessary, but it was imperative on the defendants to have placed the employment of that restraint on record. The Commissioners had most properly instituted this prosecution.

The present proceeding would operate as a warning. It was the duty of the defendants to have made the entries, and having failed to do so, they were subject to the consequences. But under all the circumstances, justice would be satisfied by the defendants paying the costs of the prosecution, which he understood would be £150, and he ordered Dr. Maddock to pay a fine of £50 on each of the indictments, and Mr. Perfect £50 on the indictment against him.

SIR CHARLES M. CLARKE.

A dinner is to be given to this distinguished physician on his birthday (May 28). The preparations of the Committee are already in an advanced state.

ROYAL COLLEGE OF SURGEONS.

Resolutions of the Council of the Royal College of Surgeons of England, respecting certain further Alterations deemed necessary in the Charters and Bye-Laws of the College; and to which they request the sanction of the Secretary of State for the Home Department.

"1. That in the opinion of this Council such parts of the Charter and Bye-Laws of the College as restrict the eligibility to the Council to Fellows residing and practising Surgery within five miles by highway or road from the General Post-Office in Saint Martin's-le-Grand, should be abrogated.

"2. That in the opinion of this Council such parts of the Charters and Bye-Laws of the College as restrict the eligibility to the Council to Fellows not having during the five preceding years practised Midwifery or Pharmacy, and require a Certificate thereof by three Fellows, should be abrogated; and that instead thereof a Certificate by three Fellows, and a Declaration by himself, that the person nominated to be ballotted for as a Member of the Council does not practise as an Apothecary, be required.

"3. That it is the opinion of this Council that the Medical Qualifications of those about to engage in the practice of Surgery, or in General Practice, should be tested by the Royal College of Physicians.

"4. That the Council of this College are prepared to form and superintend a Board of Examiners in Midwifery, or to co-operate with the Royal College of Physicians in the institution of Examinations for testing the qualifications of Practitioners in Midwifery.

"(By order)

"EDMUND BELFOUR, *Secretary.*"

19th and 24th March, 1851.

Gentlemen admitted members on Friday, March 21, 1851:—Edward Robert Bickersteth, Liverpool; James Strange Biggs, Devizes, Wiltshire; George Earle, Beverley, Yorkshire; Thos. Fuller, Brighton, Sussex; William Henry Gatty, Market-Scarborough, Leicestershire; Charles William Goodall, Normanton-on-the-Woulds, Nottinghamshire; Constantine Holman, Hurstpierpoint, Sussex; Moses Morgan, Banbury, Oxfordshire; Charles Nairne, Lambeth; George Wm. Pettinger, Sutton-upon-Trent, Nottinghamshire; Wm. Andrews Rogers, Stanmore, Middlesex.

SOCIETY OF APOTHECARIES.

Gentlemen admitted members on Thursday, March 13, 1851.—John Wright Baker, Derby; Martin B. Lamb, Forfar County; Johnson Martin, Lancashire; Thomas Plunkett, Edinburgh; David Pestell Thomas, Ravenstone, Leicestershire.

Gentlemen admitted members on Thursday, March 20, 1851:—Andrew Bolton, Durham; Samuel Gamble, Newmarket; Henry Wigglesworth, Newbury.

OBITUARY.

February 10, at Lucea, Jamaica, Edward Binns, Esq., M.D., author of "The Anatomy of Sleep," &c.

February 16, at Glasgow, Robert Stewart, M.D.

March 8, at Green Royde, near Halifax, James Inglis, M.D., aged 37.

March 17, at Weston-super-Mare, J. A. Jacob, M.D.

March 18, at Portsmouth, Dr. James Allan, Deputy-Medical Inspector of Hospitals and Fleets, surgeon to Haslar Hospital, aged 58.

BOOKS RECEIVED FOR REVIEW.

Practical Observations on the Treatment of Stricture of the Urethra and Fistula in Perineo, illustrated with cases and drawings of these affections. By John Lizars, late Professor of Surgery in the Royal College of Surgeons, and Senior Operating Surgeon to the Royal Infirmary of Edinburgh. Edinburgh: W. H. Ligars, and S. Highley, London. 1851. pp. 91.

Essays and Notes on the Physiology and Diseases of Women, and on Practical Midwifery. By John Roberton, formerly Senior-surgeon in Ordinary to the Manchester and Salford Lying-in Hospital. London: J. Churchill. Manchester: Sims and Dinham. 1851. pp. 530.

On the Causes, Symptoms, and Treatment of Spermatorrhœa. By M. Lallemand. Translated and Edited by H. J. McDougall, Fellow of the Royal Medical and Chirurgical Society, &c. Second edition. London: J. Churchill. 1851.

Dr. Hooper's Physicians' Vade-Mecum. New edition, considerably enlarged and improved, with an Outline of General Pathology and Therapeutics. By W. Augustus Guy, M.B., Cantab., Fellow of the Royal College of Physicians, Professor of Forensic Medicine, King's College, London, Physician to King's College Hospital. 1851. pp. 576.

Cases in Midwifery, by the late John Green Crosse, M.D., F.R.S., arranged with an introduction and remarks. By Edward Copeman, M.D., F.R.C.S., Consulting Accoucheur to the Norwich Lying-in Charity, and Physician to the Norwich Magdalen. London: J. Churchill. Norwich: Stevenson and Matchett. 1851. pp. 228.

TO CORRESPONDENTS.

Communications have been received from Dr. Burne, Dr. Tilt, Dr. Radford, Mr. Harvey, Mr. Humphry.

We have received a letter from the reporter of the *Lancet*, requesting our insertion of the annexed note, which was omitted in our report of the debate on Dr. West's paper, extracted from that journal. We have much pleasure in complying with his request.

* We can assure Dr. West that no one would regret more than we should any error in a report in this journal. But surely Dr. West might have seen or explained that the "mistake" to which he alluded consisted simply in the substitution of the word *think* for *hear*—hardly, however, a mistake, taking the context into consideration. However, the expression of such a regret could be in things but honourable to Dr. West. Dr. Lee sufficiently vindicated the correctness of the report, so far as the use of expressions which Dr. West declared were not employed, and we challenge Dr. West to show a single sentence, a single expression, to which any "ungenerous intensity" was "added." We are not responsible for the opinions of a speaker, as Dr. West must know. With respect to "additions" to Dr. Lee's speech, the consist merely of an occasional word or few words, to elucidate more clearly *facts* which Dr. Lee mentioned somewhat hurriedly in his rather energetic address. The additions Dr. Lee made did not interfere with the truthfulness of our report, but added to its value; no "alterations," as Dr. West stated, were made. In the present report we are indebted to Dr. Murphy for references to the cases mentioned by him in his speech.

Reporter of THE LANCET.

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho.

OF THE

CAUSES, DIAGNOSIS, AND TREATMENT

OF

OBSTRUCTIONS OF THE INTESTINES.

By JOHN BURNE, M.D.,

Fellow of the Royal College of Physicians, late Physician to the Westminster Hospital, Lecturer on the Practice of Medicine, &c., &c., &c.

Read at the Quarterly Meeting of the Bath and Bristol Branch, March 26.

The frequency of obstructions of the intestinal canal, the variety of causes, the difficulty of diagnosis, the diversity of opinion as to treatment, and the imperfect consideration given to the subject hitherto, have without doubt determined the Royal College of Surgeons to select for competition "The Causes, Diagnosis, and Treatment of Obstructions of the Intestines within the Abdomen."

The danger that always attends and the fatal issue that too often results from intestinal obstruction have induced me to bring this subject before the Association, satisfied that the members recognise its great practical importance, as well as the great principle that the alleviation and cure of disease is the proper aim of all our studies, researches, and labours; satisfied, also, that the collective experience of this assembly will go far to determine the most rational and most promising treatment.

The CAUSES of obstruction may be divided into—

1st. *Intrinsic*, or those causes which affect the intestine from *within*.

2nd. *Extrinsic*, or those causes which affect the intestine from *without*.

3rd. Those causes which do not range themselves under either of the foregoing divisions.

The *intrinsic* causes embrace—

a. Accumulations of ingesta, taken as food or otherwise.

b. Pathological, or, more correctly speaking, path-anatomical conditions of the intestines, namely, intra-intestinal tumours, stricture from scirrhus or other organic cause, and organised bands stretching across the channel of the bowel.

c. Enteroliths, or intestinal concretions.

The *accumulation* of ingesta, in the form of residuary alimentary matter or fæces, may be seated in the *small intestine*, in the *cæcum*, the *colon*, or the *rectum*; in the cæcum more commonly as an impacted mass, in the colon as a mere accumulation, in the rectum as a tough or friable hard ball: the last more generally in females. In addition to these causes are ingesta of an insoluble indigestible character, as pieces of bone, of sinew, of apple, fruit stones, seeds, magnesia, sulphur, and the like; also hard substances accidentally or intentionally swallowed, of which medical records furnish a catalogue of extraordinary instances.

Of the *pathological* causes. *stricture* from scirrhus is the most frequent, and is located more generally at the termination of the sigmoid colon in the rectum, often indeed in the rectum itself, but here, though it narrows, it rarely obstructs the channel of the bowel completely.

In the *cæcum*, too, disease is not uncommon, the morbid condition being *contraction* of its cavity from thickening and induration of the submucous and subserous areolar tissue, the product of previous inflammation; but this contraction, again, seldom leads to complete obstruction.

The most remarkable cause of obstruction from morbid growth is that of *organised bands* stretching across the cavity of the gut, like a net-work, entangling the fæces, and producing sooner or later a total obstruction. These bands are met with in the rectum likewise, and are supposed to result from a muco-enteritis with effusion of fibrin and consequent adhesions, which, acted on by the peristaltic power of the bowel and the fæculent matter, become elongated, and persist thereafter in the shape of organised bands. Obstruction in the rectum from this cause may be only partial, in the cæcum complete, of which a remarkable case is related in my first "Memoir on the Cæcum and Appendix," in the 20th Vol. of the "Medico-Chirurgical Transactions."

Enteroliths are formed either in the intestinal canal itself, and are true *intestinal concretions*, or they are formed in contiguous viscera, and find their way into the intestinal canal; as, gall-stones and pancreatic calculi. Those originating in the intestinal canal may form upon a nucleus of effused fibrin or blood; or around some foreign body by the aggregation of the salts of lime and other matters; or may be formed of indigestible fragments of food, as woody fibre, the husks of fruit, and the like. So in countries where oatmeal is a common article of diet—in Scotland for instance, they are made up of the husks and beards of oats.

According to the authority of the Monros, many concretions have been found in the same individual. A single concretion may lodge and produce a complete and fatal obstruction; or may become impacted in a diverticulum, or in the appendix vermiformis cæci, where, by continued irritation, it may produce a perforative ulceration, followed by peritonitis and obstruction, in this case sympathetic.

The *extrinsic* causes embrace—

Strangulated hernia.

Adhesion of a convolution of intestine, after the operation for strangulated hernia.

Twist of the sigmoid flexure of the colon.

Diverticula.

Pseudo-membranous bands attached to the mesentery and peritoneum.

A pouch or hole in the mesentery.

Tumours extra-enteric.

The *adhesion* of the opposite free surfaces of a convolution of intestine, previously strangulated and relieved by operation, has been witnessed by myself in one instance. It is rare, because of the precaution taken by surgeons after the stricture has been divided to draw out the gut, and to separate any adhesions before returning it into the abdomen. In the instance mentioned, the operation had been performed by an

excellent surgeon, the late Mr. White, and it is probable the agglutination may have again taken place after the return of the gut. It is worthy of remark, moreover, how slight an agglutination, separable by the least force, may be sufficient to obstruct the action of the bowel and prevent recovery.

Twist of the sigmoid colon, with or without laceration, is favoured by a relaxed state of the meso-colon, and may be caused by a sudden blow or movement; or, as O'Beirne suggests, by the sudden propulsion into it of excrementitious matter from above. The twist may be half a rotation, or, it may be a turn and a half, sufficient in either case to produce an invincible obstruction.

Twist of the small intestine, the axis being the mesentery, occurs also as a cause.

The *diverticulum* is an abornal appendix to the small intestine, often several inches in length and wide as the bowel itself, communicating openly with the gut, but closed at its distal extremity. When congenital, it often hangs unattached in the abdomen, but occasionally a band proceeds from its blind extremity and adheres to some point of the mesentery or peritoneum, and under this band convolutions of intestine may become strangulated and cause obstruction.

Pseudo-membranous formations in the shape of organised bands, the product of previous inflammation, may also incarcerate the intestine. To these the female sex, in the opinion of Rokitansky, is more prone than the male, the pseudo-membranes being frequently attached to the internal sexual organs.

The *third division* of causes includes—

Intus-susception.
Enteritis.
Colica a plumbo, and
Spasm of the intestine.

A *spasmodic constriction*, though rare, must be recognised as a cause of obstruction. In a case which occurred to Dr. Todd, and proved fatal in about thirty hours, there was found a contraction in the lower portion of the ileon, from which the transition to the dilated portion above was abrupt, and there was no mark of external compression of any kind.*

Of 169 cases of obstruction, collected with great industry by Mr. Benjamin Phillips—

63 were instances of invagination.
16 were tumours pressing from without.
19 were the results of stricture from disease of the parietes.
11 were the result of intra-intestinal tumours, hardened fæces, or concretions; and
60 were caused either by constriction, by bands, by adhesion, by the passage of the intestine through some abnormal opening, or by a twisting of the intestine upon itself.

Of the 169 cases, 133 terminated fatally, viz. 7 out of 9, or about 78·7 per cent.

Seeing that the causes of obstruction are so many and various, the *diagnosis* becomes a question for our earnest consideration, as upon it the principle of treatment much depends. In the exploration of the abdomen, by touch and by percussion, too great pains cannot be bestowed; the attention, at the same time, being alive to the fact that disease is prone to establish itself at those parts of the intestinal canal where the dimensions vary and the organization changes.

Holding in mind all the causes of obstruction, we may best guard ourselves against overlooking any; and by comparing the symptoms present in any particular case with those which are known to be proper to some and common to several, we shall be able to cast out from the list one after the other till we arrive at the single true cause, or reduce the number to a narrow limit of remaining causes, which have much in common, and to which the same treatment is applicable. By pursuing this plan of analysis the risk and fatal error of overlooking a strangulated hernia may assuredly be avoided.

In our inquiry into the special symptoms of each cause, or group of causes, we should be exact in our examination of the situations of hernia, not forgetting that strangulation may exist at the inner ring of the inguinal canal, and offer but slight evidence of tumour, especially in a stout person, Or, tumour being present in a hernial site, doubt may exist as to whether there is or is not strangulation, and an exploratory operation be required. A case of this nature occurred to myself, in which, in consultation with Mr. James, of Exeter, it was deemed advisable to explore by incision an elastic swelling at the navel.

Intus-susception, internal strangulation, and twist of the sigmoid colon, rank in the same category and have signs in common; as sudden attack and great suffering, perhaps after some strain or exertion, the patient having up to the moment of seizure been in his usual health. Signs referred to the left ilio-inguinal region may point to the sigmoid colon, while deep-seated circumscribed tenderness, with resistance to the touch and dulness on percussion, may point to strangulation or invagination, to the latter especially if blood is voided from the intestine, a sign in this case almost pathognomonic. Yet doubt will exist.

Impaction of fæces in the cæcum may be recognised by a distinct circumscribed tumour in the right ilio-inguinal region, in conjunction with a costive habit; *accumulation in the colon* by a solid feel in the course of the gut, with dulness on percussion; *impaction in the rectum* by urgent tenesmus, verified by digital exploration.

Scirrhous disease at the termination of the colon in the rectum, may form and exist without any other symptoms than those of dyspepsia, attended often with a diptheritic or apthous state of the mouth—a suspicious sign; the action of the bowels, formerly regular, having become difficult and uncertain, the dejections at the same time being scanty, soft, and very offensive; followed, sooner or later, by complete obstruction. Pains of a *neuralgic character* in the abdomen and about the trunk of the body are the frequent attendants of organic disease of the intestine, tending to occlusion of the canal.

* Observations on Intestinal Obstructions, &c., by Benjamin Phillips, F.R.S., Med. Chir. Trans., Vol. xxxiii., p. 6.

The symptoms described may excite suspicion, and suggest the necessity of examining the gut itself, in doing which tact is required, for if the course of the rectum be followed the finger will be lost in the hollow of the sacrum. To reach the colic extremity of the rectum the index finger should be introduced up to the knuckle, and directed across the pelvis from the coccyx to the projection of the sacrum. Not holding in mind these particulars, two persons failed to detect a scirrhus in the case of a gentleman who had been under my care, and in whom the symptoms led me to suspect disease, which, on examination, I was just able to detect with the tip of the finger at the colic extremity of the rectum. On this being announced a consultation was desired, and another physician was called in. He failed to reach the disease; upon which a surgeon was requested to meet us. It happened that the surgeon, not being able to keep his appointment, visited the patient alone, and, having made an examination, assured him that there was no disease. Next day we all met, when both these gentlemen were able to satisfy themselves of the existence of a scirrhous stricture.

The existence of *spasm* as a *cause* is indicated by intense exacerbating pain, restlessness, the absence of febrile movement and of the other symptoms of inflammation, and by the successive development of the signs of obstruction.*

The signs common to all obstructions are constipation, pain, vomiting, and depression of the powers of life; and in direct proportion as these are sudden and violent so is the danger. So tight sometimes is the strangulation from a diverticulum that gangrene and death will ensue in less than forty hours.† The violence of the symptoms may in some degree assist our diagnosis. In the obstructions from fæcal accumulation the countenance does not betray extreme suffering, nor is the general aspect that of imminent danger; accordingly, these cases will hold on day after day, yielding at length on the fourth or sixth, or as late as the tenth day.

A sign of some interest, and in part diagnostic, is the powerful peristaltic action often observed, so powerful as to be obvious to the touch and sight, like a snake coiling and moving in the abdomen. This effort of nature to overcome the obstacle is a sign common to most obstructions where the cause is mechanical; with the exception, however, of strangulation, in which, as in enteritis, there is a perfect *stillness* in the abdomen. This differential sign, if verified by others, would determine between obstruction from strangulation and from other mechanical causes.

Tenesmus and resistance to the passage of enemata point to the rectum or sigmoid colon as the seat.

Blood voided per alvum indicates invagination.

Tumour, deep-seated resistance to the touch, with dulness on percussion and pain and tenderness, indicate the point of obstruction; also the point is indicated when injections reach a certain spot and there stop, and the intestines propel their contents downward to the same spot and no further. It is said that the vomiting and pain are more severe when the obstruction occurs in the small than in the large intestines, and there may be some truth in the remark, but the exceptions to the rule are many. It has also been said that if the urinary secretions be copious the obstacle must be far removed from the stomach, and *vice versâ;* but the exceptions to this rule are also many.*

With every aid that our present knowledge can supply, the diagnosis will often be perplexed in consequence of the great diversity in the situation of the colon, and of other abnormities in the cavity of the abdomen.

The *treatment* of obstruction of the intestines will depend much on the opinion formed of its cause. Should a strangulated hernia be discovered, the established remedies leave no doubt as to the course to be pursued. Should the symptoms favour the belief that the obstruction is caused by an accumulation of fæces, the question at once arises,—What, and to what extent, *purgative* medicines should be administered? a question to be determined partly by the acute character of the symptoms, and partly by the manner in which purgatives are borne by the stomach.

In any case it may be proper, at the outset, to give purgatives in strong doses, as colocynth, calomel and opium, followed by senna and salts, the dose to be repeated in six hours. But these proving ineffectual, are we to persist in the further and frequent use of them?

The presence of a fæcal obstruction seems so naturally to call for the aid of purgatives, that one is tempted almost irresistibly to persevere in their administration, even though the stomach reject them; and such has been the too general practice. But observation and experience teach us to pause in this course, so frequently do we find that the strongest purgatives, resolutely

* *Ileus.—Spasmodic contraction of the Ileon; Death in about sixty hours.*

— ——, aged 5 years, was admitted into the clinical ward, Lydia, No. 7, Guy's Hospital, on Sunday, the 25th of November, 1849, at 11 o'clock, A.M., under the care of Dr Cholmeley. On admission, the boy complained of severe exacerbating pain in the abdomen, and cried much. The abdomen on exploration presented nothing abnormal. The little patient was restless, moving about the bed from side to side, generally on his hands and knees, sometimes lying on his back. When on the back he drew his limbs up; when on his knees he would move his head from side to side in agony. The tongue was yellowish and thickly furred, the face very pale, the features contracted, and marked expression of great suffering; pulse 156, rather sharp; constipation.

It was stated that on the previous evening, Saturday, the boy was seized, while spinning his top, with a violent pain in the belly, which had continued until his admission. He had taken rhubarb and was now ordered castor oil and a fomentation.

In the evening of Sunday, vomiting supervened, the belly was becoming tense, and his sufferings aggravated. Hirud. xii. abdomini; Calomel gr. ss; Opii, gr. ½; every three hours. At ten P.M., venesection to five ounces, followed by temporary relief, but the pain having soon resumed its violence. Hirud. xii. were repeated. These leech bites bled all night, and although on Monday the pain abated, no dejection occurred, and the little fellow being very much exhausted died on Tuesday morning early, about sixty hours from the attack. A few minutes after he appeared to be dead, a great quantity of fæces passed.

On dissection eighteen hours after death, the only abnormal condition discovered was contraction of the small intestine in three places; one several inches in length, the two others annular and three inches apart, inclosing in the intervening space fæculent matter, heterogeneous, many coloured, and undigested, like the grumous stool of a child.

This must be regarded as a rare example of obstruction from spasm of the small intestine, produced by the irritation of its contents; and death may have resulted partly from the intense suffering, partly from exhaustion following the excessive loss of blood.

† *Medical Times*, August 24th, 1850. H. W., age 19, in 38 hours.

* Phillips' paper, p. 17.

administered, are not only given in vain, but have a prejudicial effect, which compels us to desist; and yet by and bye the bowels act and the patient recovers. To what extent then are we called upon to prescribe purgatives? My own experience decides in favour of limiting their use, and the experience of the profession is fast tending in that direction.

It must be remembered, that often the intestine above the obstruction is itself making most powerful efforts to overcome the obstacle, as is evidenced by the striving action of the convolutions attended with acute suffering. Can good, then, arise from urging the intestine to greater efforts? We may truly answer—No. On the contrary, serious harm; for the irritation of purgatives may aggravate the tendency to inflammation, a tendency always present; and certain it is, that they aggravate the irritability of the stomach, encourage and increase the vomiting, and combine with the disease to exhaust the powers of the patient. This they do by exciting not merely more frequent vomiting, but by actually inducing a secretion from the stomach and upper portion of the intestinal canal to an extent which drains the blood of its more fluid constituent, exactly as does the Asiatic cholera. The continued use of purgatives, then, is objectionable on this score, besides that it is ineffectual.

On what remedies then are we to rely? Calomel may be admissible once in twelve hours, in full dose, if the stomach do not reject it; but the remedy that gains favour by experience, and promises the best results, is *opium*, crude in the first instance, afterwards in the form of the salts of *morphia*.

The criterion of the extent to which opium should be given is the degree and frequency of the pain, and on this we may fairly rely. Opium in the dose, first of a quarter then of half a grain, and later the acetate of morphia in the dose of a quarter of a grain, may be repeated every four hours so as effectually to relieve the pain; and, if it should narcotize the patient in any slight degree, so much the better.

A very instructive example of the propriety of this treatment occurred at Tiverton, in January, 1850, my friends Mr. Gervis and Dr. Paterson, in conjunction with myself, being in attendance. In this case purgatives were given with perseverance till their ill effect in keeping up the vomiting and aggravating the throes of pain was so obvious, and the powers of life were sinking so rapidly, that we were of one mind as to the necessity of suspending them and of relying on opium. This course having been adopted, the vomiting diminished, the morphia soothed the pain, the patient slept during the night, and the obstruction yielded on the following day.

In another case to which I was called in consultation, some years ago, every resource had been tried, fæculent vomiting was present, the powers of life were at a low ebb, and all treatment was abandoned, morphia excepted, which, in doses of a quarter of a grain, was exhibited as the throes of pain returned. On the tenth day the obstruction yielded and the patient recovered. Very lately also, a case of obstruction has been treated at Guy's Hospital successfully with opium, to the exclusion of other means.*

Although experience may decide us to abandon the frequent repetition of purgatives, it sanctions the occasional exhibition of a saline aperient,—as the *sodæ potassio-tartras*, in the state of effervescence, which salt, in the dose of one drachm, often proves grateful, and tends to liquefy the fæces; but even this should not be repeated oftener than once in twelve hours, as, independent of other reasons, salts produce distressing thirst.

In obstruction from fæces impacted in the cæcum, there being seldom so much irritability of the stomach, purgatives are more admissible, and, conjoined with calomel and opium, constitute the main treatment. Here, however, saline aperients are particularly valuable; and it does happen, that the stronger purgatives of senna, salts, and jalap, are efficacious. Yet, as the impacted mass requires time to be liquefied, purgatives should not be pressed too assiduously. When fæces are impacted in the rectum, the mass requires to be broken up, and extracted by mechanical means. When the symptoms lead to the inference that the obstruction is either from internal strangulation, twist of the bowel, or intus-susception, we recognize here invincible obstacles which forbid the use of purgatives in any form or dose. All the resources which medicine can supply avail nothing. Under these desperate circumstances, with no other prospect than prolonged torture, and inevitable death, desperate remedies are justified, may we not say demanded? The obstruction admits of relief if the parts involved could be got at, and surgery has made the bold attempt. My friend Mr. Hilton has opened the abdomen twice, though unsuccessfully, and has had occasion to regret the omission of the operation several times, once in the last summer, where a *post-mortem* examination proved the diagnosis to have been correct.

However hazardous to life wounds of the peritoneum may be, the dread which formerly deterred surgeons from making incisions into the abdomen no longer exists; they are of constant occurrence in operations for hernia, and recovery after them is common. Dr. F. Bird has made small incisions into the abdomen in eighteen cases as a means of diagnosis or relief, and in no case did a bad result ensue from such incisions. Nor is recovery unfrequent after the incisions of great extent in the modern operation of ovariotomy. On this ground, then, need we hesitate? That which makes men unwilling to risk an operation, is the doubt which involves every case as to the exact seat and nature of the obstruction. But doubt will ever remain. Weighing all the circumstances, and judging as best we may of the seat of the obstruction, and an operation having been determined on, is it advisable to open the abdomen at the particular spot? In cases where the nature of the obstruction is clearly indicated, the incision may be made as near as practicable to that spot; but where the point of obstruction is not well defined, if the abdomen

* *Medical Times*, August 24, 1850.

is opened on one side, and the cause of the obstruction proves to be on the other, the operation will have been performed in vain; and the probability of such a result is great. Only within a few weeks two friends of mine differed in opinion, the one thinking the obstruction was near the cæcum, the other in the sigmoid colon. The same difference of opinion existed between Recamier and Dupuytren, two eminent men.* How then decide? In the midst of such difficulties would not the large incision in the median line, as practised in the Cæsarian section and in ovariotomy, be preferable? Would it not afford the best chance of discovering and removing the cause of obstruction, wherever seated?

This proceeding my own opinion would countenance; it has been practised on various occasions by eminent surgeons—by Messrs. Hilton and Erichsen recently, and is recommended by Mr. Phillips, but its propriety must be decided by experience.†

Of the treatment of obstructions from scirrhus of the rectum much need not be said. It is in vain to expect relief from medicine. Nor can relief be hoped for from attempts directed to the stricture itself, which force might lacerate, but could not dilate, and surgeons wisely desist. It may, perhaps, be possible to pass a gum elastic catheter through the stricture, even when high up, though I have seen the late Sir Astley Cooper make the attempt and fail; but, supposing this accomplished, it would be hazardous to inject fluid with a view to liquefy the fæces and favour their escape, for force must be employed which would endanger the rupture of the colon, distended already to the utmost. One resource remains, scarcely preferable to death perhaps, but which it is our duty to suggest—the opening of the colon, after the plan proposed by Callisen and practised by Amusat and others. This may succeed, and an artificial anus being established in the left loin, life may be prolonged.

---

* Phillips, *ibid.*

† *Extract from Mr. Phillips' paper.*

Hevin, Menschidg, Boyer, Dupuytren discourage an operation.

Bonnet agitates the question but leaves it to be resolved by experience.

Manoury recommends gastrotomy before the inflammation is considerable, the incision to be made near the spot indicated.

Otto says, when the powers of life are in all their integrity no reasonable surgeon would operate; but after all remedies have been employed fruitlessly, the powers are so exhausted that the patient cannot bear up against the operation; or the bowel may have become gangrenous.

A case detailed by Velse in which Neck was consulted, pronounced the case intus-susception, recommended an operation, which was performed at the spot indicated. An invagination was found, the gut was gently withdrawn, and the patient survived twenty years.

Fuschius described a case of gastrotomy for invagination—successful.

Phillips' Ibid.

Erichsen's case was twist of the sigmoid colon, the operation in the median line, the twist detected and relieved, flatus and fæces passed, the obstruction done away, but the patient sunk and died. The operation performed at nine A.M,. lasted one hour, patient much exhausted. At five P.M. passed a fluid motion with much flatus, relief, spoke cheerfully. No return of vomiting after the operation. At eight P.M. he passed another fluid, fæculent, and copious motion, but almost immediately afterwards sunk back on the pillow and expired, being eleven hours after the operation.

By examination post-mortem.—The obstruction was found to have existed at the end of the transverse colon in the left lumbar region, the meso-colon of the sigmoid flexure being loose and admitted of partial twist. The bowels empty, channel free, showing that the cause of obstruction had been removed by the operation.

Query.—Did not the patient die from exhaustion? He took beef-tea, but no mention is made of other support.—*Braithwaite's Retrospect*, vol. xxi, 1850, p. 240, from *Lancet*, Jan. 26, 1850, p. 108.

The feasibility of this operation is placed beyond doubt by no fewer than three successful cases, lately published in the 33rd volume of the Medico-Chirurgical Transactions; the operations having been performed respectively by Mr. Field, Mr. Clarkson, and Mr. Pennell. The region, the left lumbar, selected for this operation, is most favourable, there being a space on the outer margin of the quadratus lumborum muscle, where the wall of the abdomen is thin, and admits of the colon being opened without wounding the peritoneum. By Mr. Field and Mr. Clarkson, the operation by transverse incision was preferred; by Mr. Pennel, that by the vertical incision. By Mr. Field, difficulty was exprienced in distinguishing the gut, fascia having been mistaken for it, a difficulty to be obviated by recollecting that the tissues to be divided, as stated by Velpeau are—

The very thick skin.

The cellulo-adipose tissue.

The origin of the transversalis muscle or its aponeurosis, and a *second* layer of cellulo-adipose tissue; of which a mass lying between the colon and the transversalis must be dissected through, and much of the fat removed before the bowel can be reached.

The relief consequent upon this operation is complete. But, as time advances, a decided disposition in the outer orifice to contract manifests itself, and leads, eventually, to renewed difficulty and danger. Would tents of sponge densely compressed, as used by Dr. Simpson to dilate the uterus, have power, by expansion, to keep the orifice patent?

The inflammation developed in cases of obstruction may call for the *abstraction of blood*, either from a vein or by leeches; but, inasmuch as the inflammation is the consequence, not the cause, of the obstruction, blood should be drawn cautiously, with a view to its control, for it cannot be extinguished, the cause remaining. Moreover, when the cause of obstruction is not insuperable the signs of tenderness and pain (which would seem to demand the loss of blood) are due to irritation and spasm rather than to inflammation, and are best relieved by *opium;* and hence the value of this remedy. The alleviation of pain, indeed, is a main point in the treatment of obstruction from any cause, for pain may destroy life; and in proportion as pain is urgent so should opium be given. In a case related to me by Sir Astley Cooper, of obstruction caused by the lodgement of a concretion in the ileon, the excruciating pain destroyed life in eight hours.

If blood is drawn too freely at the outset it would leave the patient ill prepared to bear up against prolonged suffering with want of nourishment, and might in this way turn the balance against him. In the case of intus-susception, not relieved by operation, the only chance of life is the separation of the invaginated portion of the gut, gangrene having first occurred; a process which requires time: so that if the powers of life have been reduced by excessive blood-letting, as well as by the disease, the patient will sink before nature can accomplish her task. Blood, therefore, should be drawn with circumspection.

Fomentations and warm baths are valuable adjuvants; they soothe pain, relax spasm, and, by diminishing suffering, save power.

Of all the remedies at our command, *enemas* in conjunction with opium, are perhaps the most essential, and, where the obstruction is not invincible, contribute more than any others to bring about a happy termination. Enemas, composed of bland fluids, should be injected twice in the day, to the fullest extent the bowel will receive, by the aid of O'Beirne's colon tube, a most valuable instrument in these cases.

Among the other remedies employed as a last resource are *tobacco, fluid mercury*, the *cold douche*, and *galvanism;* the two last said to be successful occasionally. But mercury is of no use as far as I have seen, and is otherwise open to great objection. Tobacco is a valuable, because often a successful, remedy; but on account of its poisonous properties it is administered only in the form of enema, the infusion for which, on the score of safety, should not be stronger than fifteen grains to a few ounces of boiling water.

Strychnia may deserve notice, and has been given in one case, in the dose of 1-16th of a grain dissolved in distilled vinegar, with remarkable success.

I have now brought to a close a subject of deep interest, treated with prolixity I fear, but not exhausted. Seldom is the medical practitioner placed in a more distressing situation than when attending a case of obstruction he finds his resources exhausted, but the obstacle not overcome. Surrounded by anxious relatives, tormented with suggestions by obtrusive friends, he has to watch, through many long hours, sufferings which he cannot relieve, and at the last to witness a death he cannot avert. Fortunate shall I esteem myself if the consideration given to this subject, and the practical opinions elicited from this assembly, should fortify our resources, and qualify us to treat with better success these formidable obstructions of the intestinal canal.

Read at the Quarterly Meeting of the Bath and Bristol Branch, March, 1851.

Affections of the Cranial Nerves, especially those distributed to the Eye and its Appendages.

The following cases of paralysis and spasmodic affections of the nerves of the orbit are selected from many which have fallen under my notice, not so much for the purpose of showing the results of treatment when it was adopted, as to illustrate the functions of the particular nerves. I take the nerves in their numerical order, as they are known to all, and with one or two exceptions have omitted a detail of the cases which are most commonly noticed.

Loss of function in the optic nerve, (or 2nd pair,) is unfortunately sufficiently common, producing amaurosis in its various degrees; I have therefore included in the present report none of the ordinary instances of this disease. The following case was one of complete blindness from amaurosis occurring many years ago, having been under my father's care in the Infirmary here, and I extract this report from my notes made at the time.*

Case 1.—A young man, a painter by trade, and 18 years of age, was admitted in a state of total blindness. He was seized with a fit a few days before, and lost his sight from that time. He was accustomed to work a great deal in oil and lead paints, and at the time of his seizure was suffering from the effects of mercury, administered for the cure of syphilis. He remained in the wards of the infirmary for nearly nine months, and was then dismissed with his sight completely restored. During the whole of his stay he was treated upon one plan, and with the greatest activity and perseverance. The sight began to improve after he had been about a month under treatment. The following abstract of the treatment will give an idea of the extent to which it was considered necessary to push the antiphlogistic plan, and the result obviously justified it:—He had, at intervals, no less than twenty dozen leeches applied to the head; he was bled from the arm five times, and on one occasion till syncope occurred; he was bled once from the temporal artery; he had blisters to his scalp; a long issue was made about a week after his admission, and after a time a seton was made in the back of his neck; he was, moreover, during the greater part of the time, taking active purgative doses, and for a short time he took the decoction of sarsaparilla with the iodide of potassium. His mouth was also affected with mercury soon after he was admitted.

In drawing attention to this as one of the very few cases of complete amaurosis that are cured, I must express my belief and fear that the patient, if he was treated now, would have so much less chance of recovery, as the treatment would be, in all probability, less active and decided.

Case 2.—Sarah Merchant, aged 21, admitted June 20th, 1849.† Has had an affection of the right eye for two years, which gives rise to considerable inconvenience. She sees nothing with the outer half of the right eye,—that is to say, when the left eye is closed, she sees only that half of an object directly before her which is towards her right hand.

This was a well marked instance of partial amaurosis,

* I have found, since I transcribed this case from my notes, that it was alluded to by my father in a paper "On Cerebral Diseases and their Treatment," read before the Medical Section of the British Association.

† This and the following cases were admitted at the "Bristol Dispensary for the cure of complaints in the eyes."

cases of which are met with in all forms, where patients see only the upper or lower halves of objects, as well as only the right or left sides. In this patient, as in most of these, treatment was of no avail.

Case 3.—Ann Rogers, aged 21, admitted November 29th, 1846. She states that she has had headache for a considerable time, and that suddenly about three weeks before her admission the upper lid of the right eye drooped completely. She has complete ptosis, or droop- of the upper lid, and inability to raise it at all, external strabismus, fixed and dilated pupil, indistinctness of vision with this eye, and double vision when both are open. This is, therefore, a clear case of paralysis of both branches of the third nerve or the motor oculi, with every symptom present that we should expect to see, knowing the distribution of the nerve, and without any additional symptom to render the case indistinct. She was treated with purgatives, and blisters to the temples for a time, and afterwards with the tartar emetic ointment over the brow, with turpentine internally. She continued this plan for a time, and by the middle of January was perfectly restored.

Case 4.—Joseph Gay, a miller, admitted June 26th, 1850. Has complained of loss of sight for ten days. He has tic in the face, or a painful condition of the surface, while sensation is perfect; he has partial paralysis of the muscles of one side of the face, slight external strabismus, with a fixed and dilated pupil, and no sight whatever in his right eye. He was treated at first with purgatives, and when he was seen after a fortnight's interval he was no better, but he had an additional symptom, namely, his tongue was protruded towards the left side. He was blistered about the brow and temples, and had mercurial purgatives. He was seen again a fortnight afterwards, and his sight was much improved; the pupil acted, and his other symptoms were relieved. The same treatment was pursued, and he recovered.

This is a complex case, and we must conclude, that from some congestion in the head he had complete paralysis of the second or optic nerve of the right side, and partial paralysis of the seventh (portia dura) and third (motor oculi) of the same side, with a similar condition of the ninth or hypoglossal of the left. He had, moreover, some irritation about the fifth, giving rise to the tic. The result of this case was most satisfactory.

Case 5.—A man was admitted into the infirmary some time ago with paralysis in the legs and bladder, with partial paralysis of the arms. The left pupil was somewhat more dilated than the right, although the sight was good; the levator palpebræ superioris, superior and internal recti, very much impeded in their power. He had complete power of eversion of the eye.

This is an instance of paralysis of many of the motor nerves where the symptoms are more marked, the further the organ is removed from the brain, as is so commonly the case. The nerve of the orbit that was affected was of course the third. Nothing in the way of successful treatment was effected.

Case 6.—A patient came over from Newport about two years ago with the following history:—Two days ago he discovered when he got up in the morning, having been very drunk the night before, that his sight was very much affected. He can see clearly with each eye, but with both together he can scarcely see at all. When he looks towards the left he sees double. The right eye is the one affected, and the pupil on this side is very much more contracted than on the other. There is a continued slight rotation of the ball of the eye in the socket, and the globe is rolled upwards and outwards. When he directs his eyes forwards, there is no distinct strabismus. His sight chiefly puzzles him in walking, for he is unable to judge of the evenness of the surface on which he is stepping. After a few days of active purging he became much better, and returned home.

This case is one of great interest, and the only one of the kind I have ever met with. The actual condition was one of over-excitement and action of a part of the third nerve, the great peculiarity being that it was only a portion of the *lower* branch which was thus affected, namely, the long branch distributed to the inferior oblique muscle of the eye, and the short root (as it is called,) of the lenticular ganglion, the former being proved by the rotation and position of the eye, and the latter by the contracted condition of the pupil. No other functions of the eye or its muscles seemed in any way altered. The actual *rotation* of the globe of the eye, without doubt, gave rise to his staggering gait, and his inability to walk, except as a drunken man walks. It is also particularly worthy of notice, that this patient's eye was exactly in the same condition as that of a healthy person when asleep, viz., the eye was turned upwards and outwards by the inferior oblique muscle, and the pupil was contracted.

Case 7.—Elizabeth Cole, aged 33, was admitted on the 11th of April, 1849. She can move both her eyes freely in every direction, with the exception that she is unable to evert the right eye. She sees double when she looks towards the right, but not otherwise. The pupil is active, the sight not quite so good as in the other. She was purged, and blistered upon the brow and temple for three weeks, at the end of which time she was much improved, in fact the improvement had been gradual from within a very short time after the beginning of the treatment. She could then move the eye well in every direction, but the sight, although better, was not quite so good as it used to be.

This is a simple instance of paralysis of the sixth or abducens nerve of the right side, with no other affection whatever of the motor nerves of the eye.

Case 8.—Emily Howell, aged 6, an apparently healthy and well-grown child, was admitted on the 18th of April, 1847. She had had slight internal strabismus of the right eye for a week, and upon an investigation it appeared that the only defect was an inability to evert the right eye. The sight was good, the pupil active and in a natural state, and all the movements of the

eyes and lids were perfect, except that of the external rectus of the right side.

Some purgative medicine was ordered, and when she was seen after an interval of only three days, the muscles of the right side of the face were all paralysed; the child was also giddy, but the sight was good. A blister was applied behind the ear, and some mercurial purgatives were given. She continued much in this state for three weeks, when she was seen again, and the only change noticed by her father was that she was stupid, and that her temper had become very bad, and that she occasionally tottered when she walked. A blister was applied to the scalp. A fortnight after, the paralytic symptoms were much the same, but she was falling away, and she was at times very violent, in fact almost maniacal. Some tartar emetic ointment was directed to be rubbed upon the head, by which means a suppurating surface was established, and considerable discharge escaped from it.

She became gradually worse, but lingered on until the 12th of September, about five months after the first symptom. About six weeks before her death her speech became obscure, and the left arm and leg became paralysed, whilst the right arm was thrown spasmodically about. She lost the sensation of the right side of the face, and flies crawled across her open eye without the slightest indication of her feeling it, and without the least reflex action. She could swallow to the last, but two days before she could not move her tongue at all, and she could not suck for a short time before her death. Her faculties were unaffected until about the last week of her life, when the memory became defective, and her father stated that she lost the power of saying her prayers as she used to do, forgetting line by line daily.

Here the disease first of all attacked the sixth nerve of the right side, and spreading backwards speedily involved the seventh; it was then apparently arrested for a time, and afterwards the fifth of the same side was paralysed, and ultimately the ninth. The eighth seemed to have escaped, and the disease never advanced sufficiently forwards to destroy the action of the fourth and third nerves. The diagnosis was tolerably easy—viz., some growth pressing upon the roots of the nerves in question, and such it proved to be.

Post-mortem examination.—The membranes of the brain were healthy. Upon taking out the brain from its situation the pons varolii was found to be softened and broken down, and the usual transverse fibres not at all distinctly seen. The greater part of the right side of the pons varolii was occupied by a hard rounded tubercular tumour of the size of a chesnut. The surrounding cerebral tissue was very much softened, and so was in fact, also, the whole of the interior of the right hemisphere of the brain. The edge of the cerebellum was softened, and at the points where the fifth, sixth, seventh, and eighth nerves arise, the substance of the brain was reduced to a mere pulp. There were no signs of vascularity around the softened parts or around the tumour.

Case 9.—Sarah Hedges, aged 34, came first upon the 21st of March, 1849. She had been thrown out of a cart two months before and struck the left side of her head, producing concussion and other dangerous symptoms of cerebral injury. Her condition had become chronic when I first saw her, and the following were her symptoms:—She had complete inability to close the left eye, with epiphora or watery eye, depending upon the paralysis of the orbicularis palpebrarum, and perfect immobility of the left side of the face. She had internal strabismus of this eye, with power of moving the organ in every direction, except outwards; she had numbness and want of sensation over the entire left side of the face, with a want of power of tasting with a corresponding half of her tongue; she had great difficulty in masticating her food, and found it necessary to remove it from between her cheek and her teeth with the finger. She did not taste until the food got back into her pharynx, and she had great difficulty in swallowing. The power of sensation on the side of the face was gradually improving; she could feel if I touched the eyelashes with a pen, but it produced no reflex action of winking.

In this interesting case there had doubtless been injury at the base of the brain, either effusion of blood producing a clot, which was gradually being absorbed, or a fracture across the apex of the petrous portion of the temporal bone, most likely lacerating the tentorium, and thus producing paralysis of the fifth, sixth, seventh, and eighth nerves of the left side, whilst the ninth and third were entirely unaffected. The effects of the injury were thus as completely local as it is possible for a severe injury of the base of the skull to be.

No treatment was adopted, as she was gradually improving, and only two months had elapsed since the accident.

Case 10.—Richard Long, aged 45 years, applied for advice, as he was suffering from a constant discharge of tears from the left eye. He states that fifteen years ago he underwent an operation for the removal of a tumour upon the side of the face, in the Bristol Infirmary. The operation was performed by the late Mr. Richard Smith. He has ever since been unable to close the eye of this side. His forehead upon this side is quite motionless when he speaks or alters the expression of his face, and the brow has fallen down over the eye, so as to present a remarkable contrast to the other side. He has a vertical scar upon the upper part of the left cheek, over the zygomatic process of the malar bone, running down to a point opposite to and in front of the lower edge of the ear.

Here, without doubt, the upper branches of the portia dura of the seventh nerve, or the facial, were divided in the section made to remove the tumour, showing the necessity of attending to the direction of an incision in reference to the anatomical position of the parts, for if this cut had been made parallel to the course of the nerve in question, no such unpleasant result could have occurred. The watery condition of the eye is the necessary result of the constant exposure of the conjunctiva to the air, but it was long before it

was developed in this case. The condition was of course incurable, but he was somewhat relieved by applications given to him to remove the inflammation of the exposed membrane.

Case 11.—Susan Lutton, aged 39, applied on the 3rd of November, 1847. She has suffered from her present complaint for five months, becoming gradually worse and worse from the commencement. Whenever she speaks, in fact continually, there is a sudden and powerful spasmodic contraction of all the muscles of the left side of the face; her eye is closed and the corner of the mouth is drawn upwards. She assigns no cause to her present condition, but it is extremely distressing to her. She was blistered behind the left ear, and took some purgative doses, but a week afterwards was no better. The tartar emetic ointment was then rubbed in behind the ear, and under this treatment combined with cathartic medicine, she completely recovered.

Case 12.—Wm. Rogers was under my care three years ago, having the left side of the face drawn up and contracted, and wrinkled. He says it feels as if the skin was not large enough. The lids were much corrugated, and the orbicularis palpebrarum was evidently continually acting. He has no strabismus when the eye is opened, its movements are perfect, but the sight is a little dim. He is deaf in this ear. He was blistered behind the ear, and was well purged. His hearing returned soon after the application of the blister. After pursuing this plan of treatment for a time with some slight improvement, he was given turpentine to take internally, in drachm doses twice a day. Under the effect of this remedy he speedily improved, and about six weeks after his first admission the twitching had entirely ceased and his hearing was perfect; he felt a little giddy but was otherwise quite well.

These two last cases are examples of spasmodic affection of the portia dura of the seventh nerve, accompanied in the latter instance with paralysis of the portio mollis, equally temporary. These cases are not very common. The treatment was followed by a very favourable result, from their having been seen early in the progress of the disorder.

The last case is one of general paralysis of the cranial nerves, and is transcribed from my notes taken whilst attending the Surgical Clinique at the Charité at Berlin.

Case 13.—A middle-aged man was admitted under Professor Jüngken, in the following condition:—He had a large nodulated swelling behind each ear, which appeared like an enlargement of some of the superficial cervical glands. He had ptosis or drooping of the right upper eyelid, which he was unable to raise at all, although he was able to close the eye more firmly. The globe of the eye was also immoveable and the pupil dilated and fixed. The tongue, when thrust out of the mouth, had its point directed to the right side. The sensation was lost over the right half of the face and tongue. A short time after his admission he became worse, and was unable to see, hear, or smell with the organs of sense on the right side, nor could he feel in the right nostril; the left eye had also become immoveable with a slight degree of ptosis. An issue was ordered to be made in the scalp, to be dressed with twelve peas, and purgative injections were given. He died about a week afterwards.

Post-mortem.—There was fungus hæmatodes of the glands of the neck, extending downwards to the shoulder and upwards into the pterygoid fossa, through the right foramen ovale and rotundum of the sphenoid bone into the cavernous sinus, destroying the third and other nerves, back to the sixth in this space, and partially affecting all the other nerves of the same side. On the left side the same condition existed but in a much less degree, the third being the only nerve here materially injured by the disease. The symptoms were thus all most fully accounted for by the *post-mortem* investigation.

According to the experience which I have had of cases of this nature, the order of frequency with which paralysis affects the nerves I have been alluding to, is the following. The third is most often affected, then the seventh, after these the sixth and ninth. The fifth and eighth are very seldom paralysed, and are in fact, from their deep-seated position, out of the way of cold and other accidental causes.

The anatomical relations of the third, sixth, and seventh appear to me to explain the frequency of paralysis. The two former, as is well known, enter the orbit from the cavernous sinus through the same aperture (the sphenoidal fissure) as that through which the ophthalmic veins carried back into the same sinus, the blood from the eye and its surrounding tissues. Any cause, therefore, which can produce fulness of the head, or any impediment to the return of venous blood from the brain, will produce congestion in the orbit, and is likely also to produce pressure on the third and sixth nerves. This idea is strengthened by the result of treatment, for if leeches and blisters are applied to the brow and temple in these cases, they will generally recover, when seen tolerably early after the onset of the disease. I believe that neuralgic headache, or pain in the course of the supra-orbital nerve is frequently induced in an exactly similar way.

With regard to the seventh nerve, it has to travel through a narrow and tortuous bony canal, ending at the stylo-mastoid opening, in company with a little artery which enters at the point where the nerve leaves the cranium. Here again, any increased vascularity or any cause (as cold), producing rheumatic or other inflammation of the fibrous sheath of the nerve, gives rise to swelling, and in consequence, firm pressure upon the trunk of the nerve, and paralysis. Here again, treatment by leeching and blistering freely behind the ear will generally cure the disease.

The only other remark with which I will detain the Society, will be made for the purpose of drawing your attention to the use of turpentine internally in chronic paralytic affections. We can understand and admit its

utility in rheumatic diseases, and many of these cases of local paralysis are probably due to an inflammation, (either gouty, rheumatic, or syphilitic,) of the fibrous sheath of the nerves. We *see* the great advantage of this remedy in promoting absorption of solid effused matter in cases of iritis, and why should it not have the same power upon organs and similar tissues that are out of sight? I am convinced that it has frequently cured cases under my care when other modes proved to be inefficient, and of this I have brought forward one or two examples this evening, but, as I before stated, these cases were not intended to illustrate any special mode of treatment, or any peculiar success in treatment, but I have brought them before the Society for the same reason as that for which I collected them, viz., to illustrate some of these interesting points in the physiology of the nerves.

ON THE

RIGHT MANAGEMENT OF WOMEN,

AT FIRST MENSTRUATION,

AND DURING THE PERSISTENCE OF THAT FUNCTION.

By E. J. TILT, M.D.,

Senior-Physician to the Paddington Free Dispensary, and Physician to the Farringdon General Dispensary and Lying-in Charity.

It has been shown, in a preceding paper, by what means the female organism may be best disposed to favour the first establishment of that important function which marks the advent of womanhood, and it might appear that when once this function has begun, the same careful vigilance of a mother, and of a medical adviser, is no longer required, nature being safely to be trusted with the rest. If this be true to a great extent with respect to those women whose constitutions are hardened by privations and the constant habit of exercise in the open air, it cannot apply to the management of those who are brought up in the midst of comforts or affluence, and in whom the emotional susceptibilities are often developed in direct proportion to the weakened energies of the body. It must also be remembered, that there are great differences in the mode of its first appearance, for if we attend to what happens to those in whom this function has been most healthily performed, we find that, at first, the flow of little amount, acquires by degrees a quantity, quality, and a length of duration, which becomes the critical measure of health in each individual case. It is, therefore, not unreasonable to suppose that this would always occur if nature had fair play, but while the performance of the function is impending, many exciting causes may intervene to determine an appearance before its appointed time, and that in an unusual manner. Sometimes I have known it to occur from a fall, or after an extraordinarily long walk. Thus a girl, 12 years of age, fell into a saw pit, and was surprised, on rising, to find herself bathed in blood; she washed in cold water, checked the flow, and was laid up with violent pains in the head and limbs for thirteen weeks, and did not recover her health until menstruation returned regularly, a year after its accidental appearance. Sometimes a fright, or a violent emotion, brings it on suddenly, and, as far as my experience goes, in all such cases the function is inaugurated by an amount of discharge which deserves the name of initiatory flooding. In 30 per cent., I have found this function begin by a very considerable flow; in 8 per cent. it amounted to a flooding, and lasted from eight to ten days. These facts are interesting because they are not in accordance with the general belief, and because they are suggestive of useful advice necessary for a mother, who ought to be warned of the possibility of this accident, in order that by her own frightened demeanour, and that of inexperienced attendants, the girl may not be alarmed at the occurrence. Duly forewarned, a mother will not only maintain her own composure and impart it to those around her, but she will be able to assure her daughter that nothing but what is usual has happened, and she should be informed that while waiting for professional advice, she is to keep her daughter in the horizontal position, with scanty covering, in a cool, well-ventilated apartment. Such means, with the addition, in some cases, of acidulated drinks, will effectually check any excessive discharge; but should the flooding assume an alarming extent, nauseating doses of antimony should be given, and it may be even necessary to have recourse to the local application of ice.

Case.—A young lady, aged 16, of middle stature, slender make, with brown hair and grey eyes, had been brought up in town, and the accomplishments of her education had been much more attended to than the measures which might invigorate a delicate constitution. At times she had suffered very much from headache, with giddiness and vertigo, and after having taken a much longer walk than usual she became unwell. The flow was abundant from the first, and it was allowed to continue until repeated fainting fits so alarmed the family, that on the fourth day the medical attendant was sent for. He judiciously adopted the measures previously recommended, and gave two grains of acetate of lead every two hours; that having no effect, he administered ten grains of the powdered ergot of rye every hour. Three doses had produced no favourable result, when I was sent for, the patient was cold and fainting, the pulse tremulous, and the heart's action feeble. In such a state there was no time to be wasted, so after reviving her with hartshorn, I made her swallow a table spoonful of brandy, and applied to the lower part of the abdomen a bladder half full of powdered ice, ordering large mustard poultices to be kept constantly applied to some part of the limbs; the flooding gradually stopped The patient menstruated regularly during the following months, but she was long before recovering her usual strength, and is even now subject to profuse menstruation, which, if not attended to, will eventually undermine her constitution.

In a similar case, should ice fail, it would be necessary to have recourse to surgical measures to stop the flow, but such measures should not be resorted to until the patient's fully-acquired conviction of impending danger

is sufficient to absorb the shame and vexation they would otherwise determine.

I have already stated that, from the intervention of certain exciting causes, the first appearance of this function might accidentally appear before it is due; and that, therefore, many months may elapse between the first appearance and the regular establishment of the function. Now, if this were to be carefully instilled into the mother's mind there would be less mischief done by the injudicious administration of forcing medicines to promote the return of what, in fact, ought not to have appeared so soon. The extent to which this pernicious practice is carried would hardly be credited; and as it is founded on a mistaken appreciation of what is true, the active co-operation of the profession will ever be required to eradicate so mischievous a prejudice. Neither are mothers sufficiently aware that they have no right to try experiments on their daughters, in case the accustomed tribute should not be paid with due regularity. This may depend on a cold or on some more serious disease, which would only be increased by the means usually employed to promote a return, only to be safely effected by the adoption of such treatment as may check the disease itself; and this is one of the most complicated problems of medical art.

Case.—I was lately consulted by a lady justly alarmed about her daughter's health. She was a delicate pale-faced girl, with light hair and blue eyes, and very tall and slender. She had menstruated at fourteen, without any previous disturbance; and the function had proceeded regularly for two years, but was sometimes scanty, at others profuse, and always attended by much pain. After amenorrhœa had continued several months the mother, without consulting any professional man, repeatedly gave purgatives, which increased the general debility, but did not bring on any return. She then followed up this system by administering powdered saffron in pennyroyal tea, which she had frequently given with effect to some of the poor women in the vicinity of her country house. This brought on spitting of blood to so alarming an extent that the mother then called in a medical man, who adopted measures which checked this occurrence; and very properly told her he would not answer for the patient's life if she continued to manage her daughter in so inconsiderate a manner. The girl's health improved, but had always remained delicate, and at times she had been much troubled with cough. The courses had not returned, and for that reason I was consulted. The girl is eighteen, consumptive, and little hope can be entertained of her recovery. There is no consumption in the family; and I believe this disease would not have been developed (certainly not at so early a period of life) if it had not been for the perverse love of giving medicine, which the soon-to-be-childless mother now so bitterly repents.

When there is an interruption in the return, provided there be no fever, the parent may safely permit her daughter to take additional exercise, particularly horse exercise, and should enjoin a relaxation in study. If there be signs of plethora, or of too much blood, the mother may safely give cooling drinks, and less nutritious diet, but should this state persist, it might be necessary to prevent mischief by the timely withdrawal of a small quantity of blood.

In the great majority of cases, however, the interruption of menstruation evidently depends on constitutional weakness, and then the parent may be permitted, of her own accord, to give a more generous diet—meat twice a day, with an additional glass of bitter ale or good port wine; but on no account should she commence physicing without previous medical advice. But emmenagogues and purgatives are not only given without medical advice to promote a return, but also to augment the quantity which a mother, or those who perform the duties of a mother, deem insufficient. Now, again, this would not occur if mothers were given to understand that the smallest quantity regularly discharged is perfectly sufficient to fulfil all the views of nature; and that a medical man alone can judge whether it be requisite to adopt measures calculated to promote its increase.

If the daily application to the medicine chest were confined to the male sex I should not think it worth while to allude to the subject, but as it is one of the chief occupations of women to soothe the sufferer in the hour of sickness, they fancy they *ought* to understand the secrets of a disease they can always alleviate by their tender sympathy, and they consider they have a *right* to give physic, in the hope of affording relief. Although in other respects the expectancies of girls are less than those of their brothers, they are more immediately under their mother's control, and coming in for the largest amount of maternal medicine, they often suffer from this interference, which tends to disturb the *monthly* re-appearance of menstruation—a condition which has already been pointed out as important for the healthy performance of this function.

This brings us to remark on another very important reason for watching over young women with a care proportionate to the delicacy of their constitutions, which is the fact that during the time that follows the first appearance we know not what type the function will assume; and although, in some extremely rare instances, its recurrence every second or third week may coincide with good health, still, as a rule, the monthly type is the criterion of a woman's health. This is the type assumed in the vast majority of women in every country, according to my investigations. Most of the cases which deviate from this law can be traced to an organic or to a nervous derangement of the ovaries or of the womb, so much so that when these diseases are cured the function resumes its most habitual type. On referring to my notes, I find that in twenty-three per cent. it did not follow the monthly type, in seventeen per cent. the type was three weeks, in five per cent. it was every six weeks, in one per cent. it occurred every fortnight. In one half of the three-weekly cases the type was explained by ovario-uterine disease of an organic nature or by chlorosis; and in more thon one half of the six-weekly cases the patient's health was habitually bad, owing, in two instances, to

uterine disease, which was also the case with the one that assumed the fortnightly type. That the fortnightly or three-weekly appearance depends sometimes merely on a disturbance of that nervous force which must preside over menstruation, seems to me evident, from the fact that in many cases in which the irregularity could not be explained by organic ovario-uterine disease I have been able to restore the function to its normal type by the exhibition of the sulphate of quinine.* If it be admitted that the monthly is the normal type, it stands to reason that we ought to seek its occurrence, more particularly as its adoption entails a less considerable drain on the sanguineous system, a less considerable perturbation of the nervous function, and affords to women a much longer term of immunity from suffering. It would be imprudent to attempt to bring on the return by direct and energetic means, but it is perfectly reasonable to watch carefully, towards the end of the second or third week, so as to prevent the patient being unduly excited by purgatives, or by any of the causes to which we have alluded. Even supposing these views to be incorrect, the plan recommended is perfectly harmless, and therefore deserves to be put into operation, as it offers the possibility of great utility; and it would be well to continue this unremitting attention, until the function, repeatedly accomplished with regularity, has been confirmed by habit.

In a paper upon the use of purgatives at the different periods of menstruation, lately read before the London Medical Society, I have dwelt on this subject, from the conviction that in the majority of women purgative medicines cannot be given with impunity. Brisk purgatives taken a few days before those symptoms which generally precede each menstrual epoch, often anticipate it by several days, vexing nature in one of her most constant laws, for I find menstruation to have been perfectly regular in 86 per cent. of the women I have interrogated. These views may appear exaggerated, but I am convinced that I have seen the bad results in others, and in my own practice; and in a few cases I can ascribe permanently disordered menstruation to the function having been treated by the patient in the same way as a child plays with a watch, setting the hands backwards and forwards.

These observations apply also to the frequent use of mercury; for I am acquainted with ladies, moving in fashionable circles, who seek to improve their complexion by a frequent use of calomel. They often succeed in producing a delicate, pallid, and unhealthy appearance, but it is generally at the expense of the menstrual flow, which is either diminished or suppressed by those means. In confirmation of this statement I appeal to the experience of Dr. Butler Lane.†

For women to repine against a monthly infirmity, which must have been wisely ordained, is as useless as it is dangerous not to take it into consideration; it should therefore be met by a monthly regimen; not that I wish to recommend the total seclusion enjoined by Moses, and still practised in eastern nations, nor even the adoption of a well-understood conventional expression, by means of which the Swiss ladies denote their inability to accept an invitation "*Mes cousins sont venus de Lausanne,*" or by saying with the Italian fair sex,—"*Il Marchese è arrivato, non passo andare.*" Without adopting phraseology, ill-suited to the delicacy of English ladies, is it not possible to find some excuse, if the maintenance of health is at stake, when so many can be found for trivial purposes?

Following a former division, I will now add a few words relative to the management of the corporeal, the emotional, and the mental functions in women at this important time.

I. With respect to the body we shall again, for the sake of clearness, first treat of what should be done, and then of what should be avoided. Amongst the more immediate measures to be employed to bring on the catamenia, or increase them when deficient, may be mentioned a brisk walk, particularly if the patient remain afterwards in a room raised to a higher temperature than usual. Warm drinks taken at night will also assist nature. A hip-bath either of hot water or with the addition of a few ounces of mustard will be of great assistance, and likewise mustard poultices to the lower part of the abdomen and to the thighs. The utility and mode of adapting these mild measures should be understood by all those who have girls intrusted to their care. Should the patient suffer considerably, or be affected with those strange symptoms which are well understood by the term temper, a warm purgative may be often administered with advantage the day before the flow is due, and the patient should be kept in bed the greater part of the day following, and be given a mild opiate even if there be no great local pain. If the sufferings are very considerable, and do not abate with the appearance of the flow, the medical attendant should be consulted, for though the belief prevails, that because the function is a natural one, all its attendant sufferings must be endured, this is so little true, that the proper administration of opium frequently alleviates the pains and insures the better performance of the function. From five to ten drops of Squire's solution of bimeconate of morphia, given every three of four hours until the abatement of pain, is a very good preparation

While thus deprecating the popular prejudice which prevents so many women being relieved from sufferings they were never intended to endure, it will be well to notice another equally deep-rooted and perhaps more dangerous prejudice, which makes them believe, that however great may be the discharge, if it occur periodically, it is in perfect accordance with the views of Nature. Frequently have I drawn a parent's attention to the debility and ill health, following an habitually too copious flow, and as frequently have I obtained the same answer—"She is always so;" so difficult is it to enforce the conviction that the fact of a girl *being always so* is the very reason for adopting such measures as would prevent her *being ever so.*

* On the Treatment of *Remittent* Menstruation by Sulphate of Quinine, with cases. By E. J. Tilt, M D., &c, *Lancet*, 1851.

† On Functional Diseases of the Liver, associated with Uterine Derangement. By Butler Lane, M D. London: Renshaw. 1848.

Profuse menstruation may be borne habitually by women of a florid complexion, and who have attained to their full growth; but when it is permitted in girls of a delicate frame, there are no means of strengthening such constitutions, the body never attains its proper proportions, increase of age brings with it no increase of strength, unless, as in some rare instances, child-bearing regulates the function. Even if no organic disease is set up in such constitutions, they become subjected to all sorts of nervous disorders, and the only period of health which women enjoy, is during the few days previous to each recurring epoch.

It is inherent in human nature to prefer the swallowing of medicine, however nauseous, to the irksome exigencies of a well combined plan of action, and the medical man is often asked for something to amend this symptom, but I am unacquainted with any specific capable of checking this prolific source of evil, which can only be safely diminished by the systematic adoption of the various rules I have laid down to promote the healthy action of the nervous functions, and to restrain that morbid irritability of the nervous system which stands in the double relation of effect and cause to profuse menstruation.

Before concluding what I have said relative to the means of increasing a deficient flow, I must briefly allude to the benefit often derived from the use of leeches. By the judicious application of a small number of leeches the medical man will be sometimes able to originate the fluxion of the sanguineous fluid, in accordance with the views of nature. I say the medical man, for he alone can decide whether the application of leeches is necessary, and if so, how many and where they should be applied.

As a result of what has been previously said, damp linen should be most carefully avoided; damp feet should be guarded against by the habit of always changing the shoes on returning from walking. Cold drinks should not be indulged in; nor acid drinks, for their well-known effect is to check a sanguineous flow. Balls and entertainments should be carefully avoided, for as at the menstrual period there is a greater susceptibility to atmospheric influences, the chance of catching cold is increased. Abstinence from such entertainments would also prevent the temptation of taking ices and acidulated drinks, or of dancing too much. Such are the things which should be avoided at certain times by women in good health, but if this time coincides with illness, an additional remark suggests itself. Were women made to understand that the menstrual process is a salutary function, which often alleviates many of their complaints, and sometimes obscures their true nature, they would not choose so inconvenient a time for consulting us, when by stopping at home to nurse themselves they may frequently avoid the necessity of having to seek our advice at all. They should also learn to avoid at those times, all medicine and all hitherto prescribed treatment, unless under the special sanction of the medical attendant; and every girl should be taught the urgency of communicating the fact to her medical adviser whenever she may happen to be peculiarly circumstanced during illness, for the concealment or ignorance of this important fact has often led to injudicious treatment, and sometimes permanently impaired the patient's health, or at all events prevented speedy restoration by the non-adoption of the most appropriate plan of treatment.

II. With regard to the mental and emotional faculties of woman to which I have already adverted, I shall again observe, that a solid education, or the cultivation of the reasoning powers, more than mere accomplishments, tends to keep in check the eccentric tendencies or morbid emotions. Some days before, and at the time occupied by this function, the head is often very much affected by pain, vertigo, drowsiness, or dulness, in which case it should be less severely taxed than usually; and those occupied in the education of girls should bear in mind not only this, but, likewise, that the same regimen cannot suit all, and that each particular pupil may require a different amount and quality of mental exertion. If excess of mental exercise should be avoided at such times, how much more all undue development of the emotions. This function often necessitates a much stronger appeal to the reasoning powers, or even to the religious feelings than is at first believed. An additional disagreeable is not felt by girls born in poverty and inured to hardships, but young ladies delicately brought up, in the midst of every luxury, when first subjected to this chain, are often painfully affected by so strange a necessity. "Am I to be subject all my life to this disgust?" is an expression which not unfrequently escapes a girl's lips; and if each revolving month brings back the same amount of intense pain, need we wonder if it should sometimes weigh heavily on the spirits, on the temper, and give rise to nervousness and hysteria, to increased repinings or to murmurings against Providence.

There are many reasons which a medical man may suggest to a mother, as best calculated to remove these erroneous impressions. Such as, that man was created independent because destined to govern the family, society, and nature; while woman was made dependent, tied to hearth and home by a long chain of never-ending infirmities, as if to point out the destined sphere where her activity could find more happiness, although a paler glory. Instead, therefore, of despising herself on account of fetters, evidently necessary, or they would never have been imposed, they should be worn with a proud humility, from the knowledge that in some mysterious way they seem to unite her more closely to her dearest earthly ties; from the remembrance also that if women have greater pains to endure, they are endowed with a greater capacity of joy, and that they derive infinitely more pleasure than men from the many forms of the one passion which alone harmonizes the terrible discordances of this world. In addition to these, Holy Writ suggests another, and truly the physiologist can adduce no better reason:—"In sorrow shalt thou bring forth children," was said to woman with reference to uterine parturition, and it seems to me to hold good also in that periodical function which is intimately connected with the parturition of the germ by the ovary, and is

therefore, accompanied by pains of a similar nature, only much less intense. This is so true, that I do not consider the menstrual function to be healthily performed unless it be accompanied by at least some spinal and ovarian pains. One of the most striking features of chlorosis is the total absence of such pains, and unless they re-appear to some extent, I never consider a chlorotic patient to be permanently cured.

To complete our sketch of that advice which should be imparted to mothers through the medium of the profession, so that they may duly perform their sacred duties, I shall conclude by a few remarks on menstruation during pregnancy and during lactation.

Pregnancy generally checks the periodical flow, but the exceptions to this rule are more numerous than is generally supposed. Thus I find that the flow continued in 8 per cent. In 2 per cent. it continued up to the second month, in 5 per cent. up to the period of quickening, and in one case it continued regularly up to the period of parturition—a circumstance which I have met with in 6 out of the 600 histories of the menstrual function which I have carefully taken down, and I mention the fact because, although its possibility is now admitted by many excellent observers at home and abroad, it was denied by no less an authority than Denman. Certainly a young woman should be warned of the possibility of this occurrence, to prevent alarm and attempts to suppress it, even if it were only to make her aware of the necessity of seeking the advice of the man of science, who can alone distinguish between the flooding, which it is necessary to check, and a natural discharge, which is to be respected; but as the ignorance of this circumstance might be a cause of miscarriage, every young married woman should be informed, that although perfectly regular she may still be pregnant, in order that nervous symptoms which may ensue, as well as vomiting and biliary derangement, may be mildly treated, and not by such energetic measures as might bring on abortion.

Lactation generally checks the flow up to the tenth or eleventh month, but more frequently than is generally believed, the secretion of milk coincides with the periodical flow as early as the second or third month of lactation, and this in perfectly healthy women. As it is impossible to tell which young mother will be the exceptional case, it would be judicious to prepare all for the possibility of the event, so as to preclude the chance of their resorting to measures which might check the flow, to the detriment of their own or their child's health. The medical man must also be prepared with a ready answer to the important question which will be asked,—The courses have reappeared, am I to continue nursing? Now, if the flow occur at an early period of lactation in a woman enjoying average good health, and if the child be tolerably well, I think it judicious to advise the continuance of suckling, but if it does not happen before the ninth or tenth month of lactation, it is better to wean, even if the milk still agrees with the child. I I am aware that this does not accord with the statements of many of the best writers of the last century, or with popular prejudice; but the permission I give a young mother to continue suckling her child, or to retain the services of a wet nurse, without breaking up her own arrangements, or depriving the servant of her livelihood, is countenanced to my knowledge by the experience of Dr. Trousseau, of Paris, and derives support from the following facts:—

Having carefully interrogated 78 women in whom menstruation had returned at different periods of lactation, I learned that the quantity and quality of the milk remained the same at that time in ... 34

[The thriving of the children being my estimate of the quality of the milk]

That it was diminished at the time only in 8

That it was completely arrested in 1

That it was impoverished at the time only in ... 4

[By impoverishment the women meant that it looked like whey, and sickened the children.]

That it impoverished the milk then and thenceforth in 1

That it was increased at the time in 17

That there was a rush of milk afterwards in ... 13

To test in a still more accurate manner the absence of any pernicious influence of the menstrual function on the milk, I lately requested my friend Dr. Hassall to examine microscopically the milk of a lady taken on the second day of menstruation, which had come on for the first time at the ninth month of lactation, and he reported that the milk was perfectly normal in quality.

We shall here conclude our remarks on the management of women before and after the establishment of menstruation; but the subject would be incomplete without some reflections on their management at the ceasing and after the cessation of that function; an important subject, which will form the matter of a concluding paper.

8, York Street, Portman Square.

Provincial Medical & Surgical Journal.

WEDNESDAY, APRIL 16, 1851.

In this country, so remarkable for the external manifestations of piety and purity—for the spotless appearance of the "outside of the platter," there has always been a difficulty in deciding whether we should, as a nation, virtually ignore the existence of prostitution, and that, in an economic point of view, its most disastrous consequence—venereal disease, or whether as in other countries, looking upon fornication as a natural and irrepressible result of human frailty and imperfect social organization combined, some attempt should not be made to render what is inevitable, as far as may be harmless to the

community. Heretofore, under the pressure of a spurious modesty, which would rather let the foul streams of lust and disease spread over the surface of society without check, than have publicly to point out their existence; the promiscuous intercourse of the sexes, while little if at all less than in countries in which female purity is held comparatively cheap, is in this productive, in a sanitary point of view, of an amount of social contamination, out of all proportion to the prevalence of the vice.

The immediate cause of this lamentable fact we believe mainly to be found in the absurd regulation of our charitable institutions, which, under the mistaken idea that by affording relief to the victim of prostitution they would be encouraging the vice, refuse to extend their benefits to the subjects of syphilis. The consequence is, that they are driven to seek such inefficient treatment as can be obtained at the hands of some ignorant chemist, or what is worse, return to their wretched trade still further to propagate a disease which a squeamish puritanism has refused to alleviate. The sad results attending this folly are, however, so admirably shown by Mr. Acton,* whose pamphlet has suggested the present remarks, that we offer no apology for giving them at length.

"Consider," he says, "the case of a prostitute who, having contracted syphilis, is unable to pay for advice or to lay by at her own rooms until she has recovered. Let us suppose she has been refused attendance or medicine at the institutions alluded to; is it to be believed that she will starve rather than risk contaminating a drunken mechanic who has a few shillings in his pocket. What is the result? Her own complaint becomes aggravated, she applies to the parish, which is *bound* to relieve her, take her into the house, or send her to the hospital. It is society that suffers, as instead of at first receiving a little medicine, she must now probably be maintained for three months at the public expense. But the 'harlot's progress' does not end here; she has infected a married man; he communicates syphilis to his wife, and the mother to the child. The father is afraid to confide to his wife the nature of his complaint, the woman is ignorant of the consequences until the disease has made considerable progress, and thus we have an entire family converted into 'non effective' individuals. Death overtakes a large proportion of the children thus infected, the health of the parents is permanently damaged, and he who turned the afflicted prostitute from the hospital door, may perhaps for the first time learn that he has sent abroad 'the pestilence that walketh by night,' to afflict the innocent mother and the child yet unborn."

This is no overstrained picture, but one, the truthfulness of which every medical man must recognize, and it behoves us as a portion of the duty we owe to society, to raise our voices against the monstrous folly that continues to deprive venereal patients of the benefits of our ordinary medical charities. That it is most unreasonable so to do, a moment's reflection will show, for if it be right to reject one class of maladies because they owe their origin to impurity and sin, it cannot be right to admit others equally the heir-loom of iniquity. If the consequences of the indulgence of the most imperious passion of our nature be thus hardly dealt with, the more beastly vice of drunkenness should not escape; and the diseased liver, the dyspepsia, and the swelled legs of the gin drinker, should on the same principle be denied relief.

But it is altogether as inconsistent with the spirit of toleration which marks the age, thus to visit the backslidings of a fallen nature, as it is repulsive to the dictates of Christianity, and, what will perhaps have greater weight with some minds, opposed to the best interests of society, moral and pecuniary. The abatement of the causes of syphilis must one day take its place beside the many other questions involved in the sanitary movement, and it is to medical men we must look for the means of favouring this event, the chief of which means will be the combatting the prejudices which have hitherto prevailed. Not only must the number of special hospitals for syphilis be increased, but what we contend for in the present article, our general hospitals must no longer be closed to the venereal patient. In this way alone, by admitting of an early remedy, will this fearful evil be moderated; and we most earnestly invite those of our readers who have any influence with the governors of hospitals, to urge the abolition of laws at once uncharitable and mischievous.

If at a loss for argument in this praiseworthy

* Prostitution in relation to Public Health, by William Acton, Esq.

endeavour, let them trace, as we have attempted to do, the miseries attendant upon an individual case dismissed with pious scorn from the hospital door; if they would urge the injustice and uncharitableness of the act, let them quote these words from a recent report of the Lock Hospital:—

"It is true that many of the objects of its merciful protection are sinners, suffering directly from the effects of their own profligate conduct. But is the mitigation of no evil or disease to be attempted except such as have been inherited, or have come upon the sufferer, while pursuing the path of propriety and virtue? Within the limits of how so small a circle could the benevolence of the Christian be then confined? To how few cases in our general hospitals could assistance be conscientiously extended; how many must be suffered to pine away in abject destitution. Were this a principle of conduct enjoined by Divine authority, and commended by Divine example, surely the sun would not now rise upon the unjust, nor would the rain descend upon the unthankful and the evil,—no scheme of redemption would ever have been formed for our fallen race,—nor would the Saviour himself, our great example, have healed in His day, all manner of sickness and all manner of disease among the people, without any reference to the characters of the sufferers or the causes of their maladies."

Amongst the many notable schemes which the reform mania of the present day has propounded, is that of compelling physicians and other prescribing medical practitioners to indite the prescriptions in English. Petitions are in fact in the course of signature for this very purpose, if we may believe the newspapers. What the motive may be for this meddling with the usages of the profession we cannot conceive, unless it be the impression that a degree of safety is attainable in dispensing from a prescription in vernacular, which is not so from the Latin. Whatever it be it will be a matter of little moment, as we do not believe that the legislature would interfere in a proceeding which has always worked well; but it is of importance as an evidence of the tendency on the part of the public to meddle with the medical profession, without the least reference to their welfare or convenience.

Reviews.

Essays and Notes on the Physiology and Diseases of Women, and on Practical Midwifery. By John Roberton, formerly Senior-Surgeon to the Manchester Lying-in Hospital. London: John Churchill. 1851. 8vo. pp. 530.

The chief object of the above essays appears to be the inquiry into the effects of climate on the occurrence of puberty in the female. Mr. Roberton has long been engaged in ascertaining, by the aid of missionaries and medical officers on foreign stations, the relative ages at which the catamenia appear and cease, and he has arrived at the conclusion that the supposition which has prevailed for so many years, that these events are retarded by cold, and accelerated by warm climates, is wholly without foundation.

Mr. Roberton has investigated these points in the north of Europe and America, among the Esquimaux, and in Greece and in Madeira in the south, as well as in the West Indies, in the Indian Archipelago, in Arabia, and finally, in Hindustan. The results are given in the tabular form with the following conclusions, which embody our author's opinions on the subject, and which must, unless controverted, be received as the standard authority on this interesting subject:—

"*Conclusions from the Tables.*—The inferences I would draw from this tabular view of the ages for the commencement and the cessation of the catamenia, and for the birth of a first child, are as follows:—

"1. The opinions of Haller, and all the physiologists since his time, that female puberty in the warm regions of Asia occurs from the eighth to the tenth year, is not only erroneous but wide of the truth.

"2. The age for the earliest commencement of menstruation, either in India or England, may be taken at *nine* years. The suspicious cases at *eight*, in the Calcutta column, might, however, be paralleled in this country—an instance of the kind having come under my own notice.

"3. That hence, although the *average* age of puberty in India is earlier than it is in this country, we may doubt if puberty does actually appear at an earlier period of life in the one country than in the other.

"4. For, bearing in mind that a proportion of the cases of menstruation under the age of *eleven* in Calcutta, amounting to 10·04, is to be received with suspicion, perhaps quite as large a proportion menstruate under the age of *eleven* in England as in India. Thus, if we take the tables for Bengal and the Deckan together, the per centage under eleven is 4; for the latter by itself, *i. e.*, Bangalore, Toomkoor, and

Bombay, it is 1·39 only; while, in England, the per centage is 3·15.

"5. The remarkable difference between the establishment of puberty in Europe and India, consists in the far greater proportion of Hindus who arrive at puberty at the ages of twelve, thirteen, and fourteen.

"To put this fact in a clear light I have to remark that, in England and the other European countries where the period of puberty has been ascertained and tabled, it has not been found that so large a proportion of instances cluster at any particular year of age. On the contrary, the occurrence of the sign of puberty is distributed more equally over a number of years—the twelfth, thirteenth, fourteenth, fifteenth, sixteenth, seventeeth; thus preserving, if one may say so, the graceful variety of nature.

"6. Although it is manifest from the tables that Hindu women reach the age of puberty nearly two years earlier, on the average, than happens in Europe, it does not follow that climate is the cause. Demerara and the West Indian Islands have a higher mean annual temperature than Calcutta and the Deckan; and yet we know that the negress in these colonies is not earlier than the peasant women of England."

The length of the intervals of conception is another point which has received considerable elucidation from Mr. Roberton, who was one of the first to support by accurate data the popular opinion, that suckling is antagonistic to conception. This opinion has now obtained general belief, but we are surprised that it should so long have been disputed, as it is within the scope of every practitioner of midwifery. In this section will be found many interesting observations, for which we must refer our readers to the book itself.

Under the heads of "Hysteria," "The Use of the Forceps," "On the best method of Turning," are many practically useful remarks, for a notice of which we have no room; indeed were we to indulge ourselves with extracting all the original and interesting remarks to be found in Mr. Roberton's volume, we might extend our notice to a most unwieldly length. We honestly recommend his production to our readers as one calculated to interest them in the highest degree.

Cases in Midwifery. By the late JOHN GREEN CROSSE, M.D., F.R.S., arranged (with an introduction and remarks,) by EDWARD COPEMAN, M.D., F.R.C.S., Consulting-Accoucheur to the Norwich Lying-in Charity, and Physician to the Norwich Magdalen. London: John Churchill. Norwich: Stevenson and Matchett. 1851. 8vo. pp. 228.

THE well known habit of our lamented associate of keeping notes of all his remarkable cases, has led to the publication of the "Cases in Midwifery," which will be especially valuable as statistical data, on account of the accuracy with which they were drawn up by Mr. Crosse, and are now published by Dr. Copeman. A table of 1377 labours, occurring in private practice, is given, in which are shown the following :—

1st, the average age at which labour has occurred; 2nd, the number of children, male and female; 3rd, the number of twin cases; 4th, the average duration of labour; 5th, the number of cases in each pregnancy; 6th, number of children, male and female, still born; 7th, number of cases in which instruments were used, specifying how many times they were used in first, second, third, fourth labour; 8th, the presentation; 9th, the number of deaths and the diseases which occasioned them.

These tables should be carefully compared with the results of hospital practice; for in no one department of our art is the difference between public and private practice more marked than in midwifery. In the use of instruments Mr. Crosse has been remarkably bold, having employed them in one case out of every 16 2-5th, which is far above the average of hospital statistics; but we are of opinion that this is frequently the case in private practice, when chiefly confined to the middle and upper classes of society; though, perhaps, all have not the openness to avow it. As a work of reference, this should be in the library of every practitioner in midwifery.

Proceedings of Societies.

MEDICAL REFORM.

MEMORIAL TO SIR GEORGE GREY FROM THE PROVINCIAL SURGEONS.

To the Right Honourable Sir George Grey, Bart., Her Majesty's Principal Secretary of State for the Home Department.

SIR,—On behalf of the Deputation of Provincial Surgeons to whom you accorded an interview on the 2nd of May last, the undersigned respectfully memorialize you on the subject of certain resolutions adopted by the Council of the Royal College of Surgeons of England, on the 19th and 24th of last month; resolutions to which the Council request your sanction, in reference to further alterations deemed necessary in the Charters and Bye-laws of the College.

The Memorialists recognize with the greatest pleasure the liberal and conciliatory spirit of this proceeding of

the Council, and now entertain the fullest confidence that the difficulties which have hitherto obstructed all attempts at medical legislation may readily be overcome.

Your attention is earnestly solicited once more to the propositions affecting the College of Surgeons, which the deputation had the honour of submitting to you on occasion of their interview.

The Memorialists respectfully urge upon you that an unqualified adoption of the propositions in question would equitably and satisfactorily procure an adjustment of the differences that of late have subsisted between the Council and the Members of the College.

In fact, with the exception of two points, the recent resolutions, in conjunction with those previously adopted on the 23d of April, 1850, concede what has been solicited. A membership of *fifteen* instead of *twenty* years, as a preliminary qualification for admission to the Fellowship on the part of those who were members prior to the grant of the Charter of 1843, and an abolition of the fee of ten guineas, (the requirement of which would indicate an invidious distinction between the already-nominated Fellows and those to be admitted hereafter,) would, the Memorialists are assured, unite the entire body of the College in approval of the heads of a Charter, that would facilitate and render practicable a general measure of medical legislation, which, in satisfying and elevating the profession, would correspond with the exigencies and the requirements of the community at large.

We have the honour to be, Sir,
Your obedient Servants,
W. W. BEEVER, Chairman, Manchester.

Honorary Secretaries.

PEPLOE CARTWRIGHT, Oswestry,
GEORGE SOUTHAM, Manchester.
S. A. PHILBRICK, Colchester.

PROCEEDINGS OF THE WORCESTER COUNCIL ON THE SUBJECT OF THE RESOLUTION OF THE COLLEGE OF SURGEONS.

At a meeting of the Council of the Provincial Medical and Surgical Association, held on the 5th inst., it was

Resolved,—

"That the Council hereby express their gratification that the Council of the Royal College of Surgeons have adopted a series of highly conciliatory resolutions, which go far to satisfy the requirements set forth in the memorial of this Association, which was presented to Sir George Grey, in May, 1850, and they trust that by mutual concession of both parties there is a prospect of a speedy and satisfactory termination of the long-agitated question of Medical Reform."

BATH AND BRISTOL BRANCH.

THE Quarterly Meeting of the BATH AND BRISTOL DISTRICT BRANCH OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION, was held at the Royal Western Hotel, Bristol, on March 26th, at 8 P.M., when there were present:—

Dr. Hodges, (President, in the chair,) Drs. Burne, Davies, and Tunstall, Messrs. J. Barrett, Bartrum, Cox, George, R. Godfrey, Kilvert, King, Norman, Ormond, and Stone, of Bath; Crang, of Timsbury, Flower, of Chilcompton; Drs. Fox, William Fox, Symonds, and Trotman; Messrs. Burroughs, Colthurst, James Godfrey, Lancaster, Morgan, Nield, and Prichard, of Bristol.

The Report of the last Quarterly Meeting at Bath was read and confirmed, when

Mr. NORMAN mentioned that he had seen that very day the patient Nooth, referred to in the report as having been subject to an operation for the removal of a supposed ovarian tumour. She was in good health, and the tumour had gradually disappeared.

Mr. FLOWER inquired of Mr. Norman to what he referred the cure?

Mr. NORMAN could only suppose that the stimulus of the knife had set up the beneficial efforts of the *vis medicatrix naturæ*, as no medical treatment had been adopted.

Mr. BARTRUM then read for Dr. Burne his paper on Intestinal Obstructions, (printed at page 197.)

Mr. J. BARRETT acknowledged the value of many of the suggestions in Dr. Burne's paper, and felt a little diffident in expressing his dissent from some of the opinions it contained. The use of the lancet was scarcely sufficiently acknowledged; nor the use of small doses of purgatives frequently repeated, as in cholera, where he had seen very small doses frequently taken in a dry state very beneficial. With regard to exploring operations he could not look lightly upon them; the opening of a hernia was a totally different affair from the opening of the large abdominal sac. It may be that there is no greater difficulty than to stand by and do nothing, yet it is better to do this than mischief. An old man had a firm swelling in the site of the femoral hernia, with the marked symptoms of that disease. An operation was proposed but positively rejected. Small doses of castor oil were swallowed, and enemata administered until the patient appeared certain to die; nevertheless, after a week had elapsed, and contrary to all expectation, as if to spite his medical attendants, he recovered.

Dr. DAVIES could not but coincide with Dr. Burne in the full and free use of opium, large enemata, and abundant fomentations, with one dose of castor oil. He did consider that large purgatives were injurious, especially saline aperients, which drained the blood of its fluids, leaving the solid contents above the part obstructed.

Mr. KING quite agreed in the absence of large purgatives; he believed the patients may often be found to die of the treatment, and not of the obstruction. He had observed the friction of the abdomen with olive oil to be attended with much benefit in promoting the action of the bowels.

Dr. TUNSTALL observed, that until diagnosis was more perfect, we were not justified in having recourse to large bleedings. As an illustration he would mention a case of lead colic. Last summer he was called to a woman who was suffering from absence of action of the bowels; she had been rubbing her bed with oxymuriate of mercury and turpentine. Large water enemata

and laudanum relieved her very shortly. He had not long ago seen a case of diarrhœa fibrinosa, (described by Grantham,) where mucus, with strings of fibrin, were passed, and yet the bowels were not relieved; the use of conium and rhubarb was effectual in doing so. This case of diarrhœa had been caused by strong and frequent purgatives.

Mr. Flower narrated a case bearing on Dr. Burne's treatment. The patient took full doses of opium, with sulphate of magnesia, whilst large water injections were thrown up through a long tube. After ten days she was conscious of violent efforts being made by the bowels, and then at last an enormous quantity of fæcal matter was voided.

Mr. A. Prichard did not agree with Mr. Barrett in the opinion, that the whole responsibility of an exploratory operation, dangerous as he described it, rested with the surgeon who performed it, as the diagnosis in such a case properly belonged to the medical, and not the surgical staff.

Mr. Barrett, some years since, had a case of strangulated hernia, wherein he had injected, with considerable force, a large quantity of water by the long tube, and with a successful issue.

Mr. Stone wished to ask if there would be any fear of rupturing the intestines by forcing very large quantities of fluid through the long tube.

Mr. Nield observed, that the experience of the last few years had shown, that with proper precaution the opening of the abdomen was not so fatal as had been supposed. If, therefore, after long waiting, the use of opium, &c., the bowels were not relieved, he considered we were then justified, after using our best judgment, especially with the assistance of chloroform, in making an exploratory examination into the state of our patient, who would not, after all, be in a worse position than he was before. He narrated a case in which a hernia had existed for forty-eight hours. She was put under the full effect of chloroform, whereby the large bulk of the intestine returned into the abdomen, and on opening the remaining tumour, the remainder of the intestine was found attached to the neck of the sac. In this case the patient was in a better position, from a large portion of the intestine having been returned, indeed it would have been wholly so but for the adhesion.

Mr. Colthurst remarked, that the various opinions given appeared to be upon an imaginary case that may or may not have happened. He had had the misfortune to watch for several days, (some sixteen years ago,) the case of a young girl in which were all the symptoms of a hernia, but which, as with the most minute examination he could discover nothing of the kind, he diagnosed as a case of intus-susception; a *post-mortem* examination, however, proved it to be a hernia of the ileum through a loop formed by one of the appendices epiploicæ, its usually free extremity being attached to the adjacent surface of the ascending colon, at the very spot to which during life his poor patient specially directed his attention as the seat of her suffering. The whole of the circumstances of this case had left a strong conviction on his mind, that were he placed in a similar position he would certainly feel called upon to make an exploratory operation.

Mr. J. Barrett again urged the impropriety of exploring, and inquired at what period the advocates for an operation would proceed? Would Mr. Norman operate if there were no local symptoms?

Mr. Race Godfrey some years since had himself laboured under symptoms of intus-susception. Whilst under a mild dose of medicine, he felt suddenly an intense pain in the left side of the abdomen—a pain of a dull aching character, with great restlessness; it lasted for ten hours, with symptoms of intense depression, until he fainted, when he as suddenly aroused perfectly well, except from the exhaustion. In this, his own case, he quite felt that he should have been most thankful to have submitted to an operation, which he was convinced would have relieved him, the spot for an incision being so precisely indicated, indeed it could have been covered by his thumb.

Mr. Norman replied to Mr. Barrett's personal appeal by observing, that a person of experience would quickly recognize symptoms of strangulated hernia, even though no tumour existed; and as to the period for operating, he certainly should not wait until the patient was in a condition to render such a proceeding hopeless. If the pain were near the canal, and even no tumour apparent, no one would doubt the propriety of operating. He mentioned two cases in which, with all the symptoms present, no hernial tumour was found, but in which dissection showed that the gut had passed through a loop in the mesentery. At the same time he considered that no one would operate unless there were some settled pain in some particular spot, as in the instance narrated by Mr. Colthurst. He well remembered that whilst he was a pupil under Cline, a man came into the hospital with marked symptoms of hernia; he was examined most carefully, and near the femoral ring there was a slight shrinking noticed, although there was not the slightest swelling; Mr. Cline, however, proceeded to the operation, and found a very small portion of the intestine strangulated, this was liberated, and the patient recovered.

Dr. Symonds considered that the proposal to operate was too generally looked upon as a *dernier resort*, and he described a case that occurred to himself of a strangulated intestine, slipped through a noose, formed by a diverticulum ilei; he narrated a case of ileus occurring in a medical man, relieved by the use of the syringe whilst in a warm bath, and this too, after opium and various other means had been ineffectually used. This plan was first proposed by Dr. Wilson. Tobacco enemata, after Abercrombie's method, 15 grs. to 1 pint of water infused for ten minutes, sometimes, in his experience, had answered. He quite concurred in the propriety of operation when other means failed.

Mr. James Godfrey wished to draw the attention of members to the great advantage of chloroform in diminishing muscular action, so much so that he quite anticipated the mortality from hernia being much reduced by the use of chloroform. He should put the patient under the full influence of this remedy, and then use the usual manipulation with subsequent enemeta. He hoped more from it than from opium. He would confess that our experience showed the difficulty of diagnosing correctly the relative position of the viscera. He had found the transverse colon displaced in cases of chronic obstruction of the lower bowel, the colon itself

being distended, and the meso-colon strained, so as materially to interfere with the diagnosis; he could but think that in such cases the surgeon would be justified in passing a trocar into the bowel to relieve the tension.

Mr. BARTRUM spoke of constipation from want of action in the bowels, the lower portion being empty, whilst the upper part was full of fæcal matter. In these cases opium was the sheet anchor.

Dr. BURNE replied by adverting to the satisfaction he received from the experience of members upholding the use of opium, to the difficulty of contending with the wishes of anxious friends to use violent purgatives and to do something; also to the diagnostic symptoms distinguishing the various kinds of obstruction, to the use of chloroform, and to the propriety of resorting to an operation before mischievous inflammation had set in, to the serious difficulty always besetting such cases, and the consequent necessity for consultation with our medical brethren.

Mr. A. PRICHARD then read his report of a few cases of affections of the cranial nerves. (Printed at page 202.)

Dr. TUNSTALL also read a few observations on the arsenic bill, already printed at page 181.

After which, the Secretary, Mr. COLTHURST, placed on the table the petition in favour of the said bill, agreed to at the annual meeting at Hull, which was signed by the members present. It has since been forwarded to William Miles, Esq., M.P. for East Somerset, who has promised to present it and support its prayer.

Treatment of Pruritus Ani and Vulvæ.

The practitioner has often to regret the failure of his attempts to relieve these distressing affections. Pruritus ani may be of comparatively little importance, except as an indication of visceral or hæmorrhoidal disease, but pruritus vulvæ is of far greater consequence, as independently of other considerations it almost inevitably leads to habits of masturbation, amounting in some cases to furor uterinus. We have recently been consulted by three or four patients, one of whom avowed that the friction commenced for the relief of the itching, was continued for the gratification of the sexual sensation which it excited, and that in spite of a feeling of the almost moral degradation, the act was repeated so frequently that the health was seriously undermined. The importance of remedial measures in such a case cannot be over-estimated.

Dr. Tornie (*Union Médicale*) has contributed a paper on this subject, in which he states his great confidence in an ointment consisting of calomel and axunge, one part of the former to five or six of the latter; the parts after being well washed to remove any eczematous crusts, are to be anointed freely with this ointment twice a day, and afterwards sprinkled with a powder containing the same proportions of starch and camphor.

Dr. Tournie relates several cases in which he has thus succeeded after repeated failures with borax, sulphureous and other washes, most of which consisted of eczema or prurigo of the labia, and lichenoid eruption of the anus.

In the pruritus vulvæ of pregnant women, nothing appeared to be successful, but it subsides spontaneously after delivery.

[In pruritus ani we have derived great benefit from equal parts of Unguent. Gallarum and Unguent. Hydrarg. Fortius.]

GERMANY.

Camphor as a Local Application in Noma.

Dr. Deutsch (*Journal für Kinder Krankheiten*, and *London Journal of Medicine*, April,) speaks highly of camphor as a local application in cancrum oris. He says:—"I do not hesitate to mention a remedy, the remarkable operation of which has been noticed by myself and others—I allude to camphor. The mode of application is as follows:—The camphor is rubbed, and moistened with a few drops of spirit of wine, so as to form a thickish mass, of the consistence of ointment; this is laid on the whole surface of the part diseased, and one-third of an inch beyond. If there be much secretion, it must be removed after an hour. The first effect of this is an arrest of the gangrene, which remains stationary for twenty-four hours, or more. A positive result now appears, the edges of the sore exhibit a line of demarcation, and granulations appear."

Ozone and Catarrh.

Our readers will remember the discovery announced by Schonbein, of a particular substance called *ozone*, which he observed to have some special relation to the prevalence of epidemic catarrh. This substance, it will also be remembered, may be produced artificially by the combustion of phosphorus, &c., and is strongly electro-negative. Its exact chemical composition and properties are still unknown, but its presence in the atmosphere has been ascertained by M. Heidenreich, (*Neue Medicinische-Chirurgische Zeitung,*) to be so constantly associated with morbid respiratory phenomena, and the intensity of the latter has been noticed by him to be so exactly proportionate to the abundance of the former, that he states his conviction that the extent to which pulmonary lesions will prevail may be predicated from the measurement of the intensity of the ozonic element. This may be accomplished by means of a contrivance which he calls his ozonometer, and which is thus prepared:—

Five grains of iodide of potassium are dissolved in two ounces of distilled water, to which half an ounce of fine starch, and subsequently two ounces more water are added. The mixture is heated for a few minutes, and five times the bulk of water is added, and again boiled. In this large bands of unsized paper are to be dipped and dried. These are cut up into strips, and preserved in stoppered bottles.

The action of the ozone on this paper must be secured from all other reactions on the iodide of starch, for this purpose a glass tube, open at both ends, is provided, into which a strip of paper is placed, and fixed at one end by a wooden plug. The glass tube is suspended by an iron wire, and to prevent the action of light, is enclosed in another tube of metal or card board.

In using this instrument, the slip of paper previously moistened is fixed to the iron wire, which perforates the plug, and is suspended within the glass tube. The reaction may be observed on the edges of the paper in from three to five hours.

Before he commences his experiments, the author tests his paper by treating it with very diluted sulphuric acid. There is no immediate change, but in about a quarter of an hour the paper assumes a faint brown colour, which gradually deepens, and eventually becomes intense. The author does not agree with M. Betz that the action of ozone on the paper is interfered with by moisture, on the contrary, the reaction has been most marked in rainy weather. He also observed that the action of ozone is neutralized by ammonia—an interesting circumstance when taken in connection with the fact that ammonia is often found very serviceable in the treatment of epidemic catarrh.

After these details respecting the physical and chemical properties of ozone, M. Heidenreich gives a table of diseases observed during two months with the corresponding indications of the condition of the ozone. He noticed among other facts that an augmentation of the ozone always coincided with marked exacerbation of pulmonary complaints, while a diminution of these coincided with decrease of ozone. When the quantity was low, he also found that there was a prevalence of affections of serous membranes, erysipelas, uticaria, &c. Rheumatic affections appeared to accompany an excessive reaction of ozone.

General Retrospect.

ANATOMY AND PHYSIOLOGY.

Has the Cerebellum any special connection with Sexual Propensity?

This is still an undecided question. Gall and Spurzheim, with a host of minor phrenologists, regard it as one of the best settled facts in phrenological science, that the cerebellum constitutes the nervous centre, which presides over the sexual instinct or function of generation; while Fleurens, Magendie, and other physiologists regard this division of the encephalon as the organ for co-ordination of muscular movements. The investigations of Muller and Carpenter show that comparative anatomy favours the opinion of Fleurens and Bonilland, but the distrust which arises from vivisectional experiments, makes it desirable to avail ourselves of every other mode of investigation.

Gall and his followers contend that injuries to the cerebellum not unfrequently cause wasting of the testicles. But M. Laissaigne found that the cerebellum of the gelding was larger, both absolutely and relatively to the cerebrum, than in the stallion or mare, so that further observation seems required to decide the question; this has been to a certain extent furnished by Dr. Davis, Professor of Physiology in the Medical College, Chicago.

This gentleman procured the brains of several bulls and oxen, all as nearly as possible of the same age and size; the cerebellum of each was carefully measured in the following directions:—1st, transversely; 2nd, antero-posteriorly; 3rd, vertically; 4th, from the apex of the inferior vermiform process to the apex of the superior process of the same name; and, 5th, transversely across the widest part of the superior vermiform process. The results on the average in the weight of the organs are as follows:—

Weight of cerebellum in bulls	13½ drachms.
„ cerebrum „	115½ „
Proportion	1—8 3-5ths.
Weight of cerebellum in oxen	13½ drachms.
„ cerebrum „	114 „
Proportion	1—8 2-5ths.

These observations confirm the examinations of Laissaigne as to the relative weights of the cerebellum in the entire and the castrated animal. The measurements of Dr. Davies also controvert the opinion held by Dr. Carpenter, that the central part and vermiform processes is the organ of the sexual impulse, as this part is absolutely broader and longer in the ox than in the bull. Hence, says Dr. Davis,—"Unless we deny the validity of the physiological law that exercise increases growth, and *vice versâ*, it must be conceded that the facts referring to the cerebella of oxen and bulls, effectually disprove any special connection between the cerebellum, (either as a whole or any of its parts,) and the sexual appetite."—*Transactions of the American Medical Association.*

PRACTICAL MEDICINE AND PATHOLOGY.

On Serous Effusion in the Cavity of the Arachnoid.—By Dr. Austin Flint.

This affection has been little noticed of late, attention being chiefly directed to effusion in the ventricles. As autopsies are generally made it is easily overlooked. The precautions to be observed are these: not to divide the dura mater with the head depressed, and to remove the brain from the cranium before incising it, and without rupture of the investing arachnoid. The fluid in the cavity of this membrane will be found at the base of the skull, and within the spinal canal. When morbid its quantity may vary from half an ounce to six ounces.

This fluid during life will settle towards the spine, and first cause pressure on the medulla, producing early derangement of respiration and deglutition. Cases are quoted where these symptoms coexisted with effusion of blood in the neighbourhood of the medulla, and in some of which death evidently began by failure of respiration, the heart continuing to act after breathing had ceased. Dr. Flint relates twelve observations of his own.

The following propositions are offered by the author as worthy of consideration:—

1. Effusion in the arachnoid cavity at the base of the brain is liable to occur, as an incident in the course of various affections, being immediately produced by cerebral congestion.

2. It is not an unfrequent cause of sudden death.

3. It produces death by apnœa, from pressure on the medulla oblongata.

4. The symptoms are, somnolency or coma, without paralysis, not preceded by symptoms of meningitis; disordered respiration; impaired deglutition; intellect not disordered, if the patient can be roused.

5. The presence of fluid in the arachnoid, compressing the medulla, is generally fatal.—*Buffalo Med. Journ.*, April and May, 1850.—*Transactions of the American Association*, Vol. 3.

SURGERY.

Mammary Abscess; treatment by Collodion.—By Dr. John Evans.

Mammary inflammation, during lactation, is exceedingly prone to end in abscess. This is owing to the great vascularity of the organ, and its loose and flaccid texture, which allows the determination of blood to it speedily to result in effusion of lymph, which, in the absence of the pressure made by denser structures, is not absorbed, but results in the secretion of pus. Thus when the breast becomes indurated under the treatment heretofore practised by the profession, of poulticing, applying liniments, tobacco leaves, &c., without constitutional treatment, it almost uniformly forms an abscess.

Disheartened by the general want of success in preventing suppuration by the ordinary means of treatment, and satisfied that the most prominent indication of cure was to overcome the freedom with which the blood is forced into the mamma, and, by compression, cause the absorption of the lymph, as is done by the roller applied on the extremities, in various forms of inflammation, Dr. Evans determined to use a complete coating of the collodion to obtain the benefit of its contraction; the result of which will be more fully illustrated by relating the following cases in which it has been used:—

Case 1.—Dec. 18th, 1849; called to see Mrs. J., suffering from mammary inflammation during lactation. Found she had bathed with liniments, applied poultices, and kept the milk well drawn from the breasts, but without apparent benefit. I could detect decided fluctuation at the point of greatest suffering. I ordered a coat of the liquid adhesive plaster, which gave very prompt relief, and the inflammation speedily subsided. A few days after I opened the abscess, which pointed, but it discharged a very small quantity and rapidly recovered.

Case 2.—Mrs. S. was confined June 5, 1850, with her third child. On the 7th, she was attacked with a chill, followed by high fever and active inflammation of both mammæ. She had suffered, after each of her previous confinements, with extensive abscess of the left breast. The secretion of milk was very profuse, and notwithstanding strenuous efforts to keep the milk drawn off by the assistance of a little girl, who drew it very freely, the left mamma became extensively indurated, and was acutely sensitive and painful at the point of the former abscesses.

I applied the collodion so as to cover the indurations completely, with the effect of promptly relieving the suffering of the patient; and by repeating the coating morning and night for a few days, the indurations were removed. The only additional treatment used was seidlitz powders, given to produce a laxative effect.

Case 3.—Mrs. McC., eight days after confinement, was attacked with mammary inflammation, attended with chill and high febrile excitement, on the 8th of June, 1850.

Gave Mass Hyd. grs. xij. with Pulv. Doveri grs. viij. in the evening.

June 9th. This morning the breast is very painful and extremely tender to the touch, great thirst, dry mouth, frequent but compressible pulse, and a troublesome cough. The bowels had not been moved. Ordered Sol. Mag. oz. ss. and an application of the collodion to the breast, and free abstraction of milk.

June 10th. Much better; says the application of collodion to the inflamed breast gave immediate relief to the pain, and the soreness has rapidly diminished. Ordered the application to be repeated.

The recovery was rapid without suppuration.

Case 4.—Mrs. P., three weeks after confinement, was attacked with inflammation of the mamma on the 24th of June, 1840. She had been previously under treatment for uterine phlebitis, from which she was recovering.

The breast was swollen, indurated, and very painful. The collodion was applied so as to cover the induration and swelling, with almost instant relief to the pain. By repeating the application the swelling subsided gradually, without suppuration.

Case 5.—July 15th, 1850. Mrs. M. had an attack of inflammation of the right mamma, about ten days after confinement. I was called the next day and found it swollen, indurated, and painful, nothwithstanding the milk had been kept freely drawn, and the breast well fomented. A coating of collodion, as in the preceding cases, promptly gave relief to the pain, and gradually removed the swelling.

In no case where I have used the collodion, except the first one reported, has the slightest suppuration taken place.

In every instance the relief from suffering has been prompt, and no inconvenience has resulted from its use in any case, except the slight smarting that attends its application.—*North Western Med. and Sur. Journal.*

Case of Erysipelatous Laryngitis, in which Tracheotomy was performed.—By J. Smiley, Esq., A.B.

[There are few cases more rapidly fatal than those of which the following is an instance. Tracheotomy is in general the only proceeding which offers a chance of life; but it happens unfortunately that the operation

has been spoken of in so disparaging terms, that the surgeon is not led to contemplate its performance, until the time has passed in which it can be done successfully]

On the 18th of May, 1850, I was called upon to visit Mrs. S—, aged 63, who was supposed to be on the point of suffocation. I was supplied with the following history of her case by Dr. Leech, who was previously in attendance on her. On the 11th of May she had feverish symptoms, and on the 14th complained of soreness of her throat. Her daughter had just recovered from diphtheritis affecting her mouth and throat; and this appeared to be a similar affection. On the 16th, Dr. Leech was called in; she had then great difficulty in swallowing, and her breathing was slightly affected; the larynx was tender to the touch, and the inside of the mouth and throat was covered with a white membranous coating. Leeches, calomel, and Dover's powder, and a cathartic, were prescribed.

18th.—All the symptoms were aggravated; she complains of soreness in one nostril, and stiffness of the eye-lids, and her breathing became so laboured towards evening that a consultation was requested, to consider the propriety of opening the trachea; but leeches and calomel, prescribed in the mean time, were followed by such relief that it was considered prudent to defer the operation till the following morning.

19th.—Early this morning her breathing became so difficult that immediate suffocation was dreaded; the erysipelas had extended from the nostril to the face, engaging the nose and right eye-lid; her distress was so great that she eagerly embraced the hope of relief that was held out to her by the operation; her sufferings were greatly aggravated by the swollen state of the epiglottis, which was incapable of performing its functions, so that fluids made their way into the glottis, bringing on violent struggling for breath. The distress she suffered from this was so great that, notwithstanding a burning thirst, she had abstained altogether from fluids for the last twenty-four hours.

At ten o'clock, A.M., assisted by Dr. Leech, Dr. Davy, and Dr. Barker, the operation was performed, and a silver canula was inserted into the trachea, when immediate relief from all the urgent symptoms was obtained.

20th.—Breathes freely through the canula; slept a good deal during the night. The erysipelas has spread, and extends all over the right ear, where the cuticle is raised in blisters. Fluids taken by the mouth still get into the larynx, and are discharged by the canula; they do not, however, now cause the same paroxysms of suffocation. She was ordered bark and wine.

21st.—Erysipelas extending; pulse 120.

23rd.—Improved; had a good night. Erysipelas has not spread since yesterday; the whole face is now engaged; no raving; pulse 108; strength increased. The rima glottidis seeming to be open, the canula was withdrawn. Liquids can now be swallowed without difficulty.

24th.—Breathes freely, both through the rima and wound, which has been left open; had a restless night; pulse 120; is drowsy, and slightly delirious,

25th.—Had a good night; pulse 92; great drowsiness.

29th.—Has continued steadily to improve since last report. The lips of the wound were drawn together with adhesive plaster this day.

December, 1850.—It is now more than six months since the operation was performed, and Mrs. S—— has enjoyed excellent health from the time of her recovery, and has felt no inconvenience whatever resulting from it. The wound healed readily, and she convalesced rapidly after the last report given above.—*Dublin Quarterly Journal.*

MIDWIFERY.

Congenital Malformation of the Œsophagus.—By Dr. AYRES.

This interesting, if not unique, specimen was presented to the London Pathological Society. It was taken from a child who was born November 9th, 1850, after a natural labour. Some gurgling sounds were observed immediately after birth. The next day it was observed that the child was unable to swallow; when applied to the breast, or when food was attempted to be given, a loud gurgling sound was produced, accompanied by struggling, blueness of the lips, impending suffocation, which continued until the whole of the milk or food returned by the mouth. A bougie could be passed only a short distance below the pharynx, when it met with an obstruction to its further progress. The case was considered as one of congenital occlusion of the œsophagus, and it was suspected that the œsophagus communicated in some way with the trachea. The child died at the end of twelve days in a state of extreme emaciation, beef-tea enemata having been administered several times a day. The autopsy showed that all the parts of the body and viscera were natural, except the œsophagus and trachea. The pharyngeal part of the œsophagus, extending to about an inch below the pharynx, was considerably dilated, and terminated rather suddenly in a cul-de-sac; a narrow imperforate band of fibres extended downwards to the stomachal portion, which latter terminated above in a semilunar opening into the trachea, about half an inch above its bifurcation. In this case all the fluids taken into the stomach could pass no further than the cul-de-sac; while any secretions of the stomach could only find their exit to the mouth by passing through the trachea and larynx.—Reported in *Medical Gazette*, Feb. 14.

THE APOTHECARIES' COMPANY v. THOMAS FAWTHROP OF HALIFAX.

COUNTY COURT OF YORKSHIRE AT HALIFAX.

ON Wednesday, the 2nd of April last, this important case was heard before James Stansfield, Esq., the judge of the County Court of Yorkshire, at Halifax. Mr. Holroyde appeared on behalf of the plaintiffs, the Master, Wardens, and Society of the Art and Mystery of Apothecaries of the City of London; and Mr. Wavell appeared for the defendant, Thomas Fawthrop,

who for some time has practised in this town as a surgeon and apothecary, under the style and firm of "J. Fawthrop and Co." The court was crowded during the whole of the day, and a considerable number of the medical profession were in attendance during the protracted inquiry.

The following gentlemen were sworn upon the jury:—Mr. J. Booth, bookseller, (foreman), J. Whitworth, Esq., Mr. D. Porter, Mr. T. Nicholl, and Mr. J. Gibson.

On the case being called Mr. WAVELL said he appeared for the defendant, and objected to his friend Mr. Holroyde opening his case until he produced the seal of the corporate body for whom he said he appeared.

His HONOUR said that he had never before heard counsel called upon to produce their authority; and after short argument said, that in order to avoid any further discussion, he would give special leave to Mr. Holroyde to proceed.

Mr. HOLROYDE in stating the case, said that he was surprised that an attempt should be made to stop him, nor could he imagine what reasons could have induced his friend to take such a course. No doubt he had some special reason in preventing the case being stated, and the jury coming to a verdict upon it. He hoped, however, that before the sun set the jury would pronounce their verdict, at all events they should have an opportunity of judging whether his honourable clients had a good case or not. The action was brought by a Society called the Master, Wardens, and Society of the Art and Mystery of Apothecaries of the City of London, against the defendant, Thomas Fawthrop, who had assumed and did now practise as an apothecary duly licensed by that honourable company, but without being duly qualified to practise as an apothecary. He must explain how it came to pass that the Apothecaries' Company had to complain of Mr. Thomas Fawthrop. Previous to the year 1815 any individual who in his opinion had sufficient knowledge, and in the opinion of the world was duly qualified, could go and attend parties who were ill and required medical assistance; and if parties got their living thereby they were in a position to obtain by law their charges for such attendance. But it was found in 1815, that a great number of ignorant persons were practising as apothecaries,—men who were not fit to be intrusted with the lives of Her Majesty's subjects,—and an Act of Parliament was passed, enabling the Society which he had the honour that day to represent to grant certificates to persons who, after passing a proper examination, should be found to be duly qualified to practise as apothecaries, and no person after the 1st of August, 1815, could lawfully practise without such certificate. If a person did so practise he rendered himself liable to a penalty of £20, which was the penalty sought to be inflicted upon the defendant in the present case. The Apothecaries' Company regarded it as a very bold act on the part of the defendant to set himself up as a member of the Apothecaries' Company in a borough of such high position as Halifax, and they had considered it their duty to proceed against him for the penalty stated. In addition, he ought to inform the jury that the certificate of which he had spoken could not be obtained as a mere matter of course. The party seeking it must show himself competent in the eyes of men well qualified to judge of his competency before he can practise as an apothecary. The learned gentlemen then read and commented upon the various clauses in the 55th Geo. III, bearing upon his case, and concluded by stating that prior to the establishment of county courts considerable difficulty was experienced in inflicting a penalty of £20 upon persons practising as apothecaries but without a certificate. They would have been obliged to take such a case as the one now about to be brought before the jury to York, which of course would entail great expense. Fortunately the Society could now protect Her Majesty's subjects in every part of the kingdom at little expense; and he was told that it was their intention to do so, and that the present was one of a series of actions which had been commenced in different parts of England against apothecaries not duly qualified. If Mr. Fawthrop could produce a certificate, he, for one, should be most proud to see it; but he should call witnesses to prove that he had practised as an apothecary and rendered himself liable to the penalty imposed by the Act of Parliament. The following witnesses were then called:—

Hannah Morley.—I am the widow of John Morley, who resided at New Pellon. He died about nine months since. Previous to his death he sent for "Dr. Fawthrop," and my son went for him; he came the day before his death, and had come more than six times before then. He felt his pulse, and gave him physic. He also looked at his tongue. We have had "Dr. Fawthrop" in our house before, and a very nice man I call him. (Laughter.) He sent in a bill. A son of mine and a daughter went for the physic. My husband was very poorly, and the "Dr." said it was an inflammation of the bowels.

Cross-examined.—This paper (the bill) came to my house. My husband was 53 years of age. We sent into the Square for medical assistance, and it was my husband's orders to have "Dr. Fawthrop" fetched. I have no reason to be dissatisfied with the attention my husband received. I cannot say whether there was any printed label upon the bottles. The "Dr." did not administer the medicine himself.

Re-examined.—My husband took the medicine sent him.

By the Judge.—The "Dr." told my daughter to call at a certain time for the medicine, and he would make it up for her. He said she was to call at half-past five o'clock.

Henry Morley.—I am a son of the late John Morley, of Pellon. He died on the 9th of last July. I fetched Mr. Fawthrop at the request of my father. This was sixteen days before his death. I fetched some medicine for my father from "Dr. Fawthrop's" in the Square. His shop was like all other doctors' shops—it had plenty of bottles in it, and I saw him make up the medicine which he gave me for my father. I saw him mix my father's medicine up more than once. I took the same medicine home and gave it to my father myself.

Cross-examined.—I went into the Square. There was a sign. The bottles had a label on like the one now shown me. The name over the door was "J. Fawthrop & Co."

Hannah Cooper.—I am the wife of Wm. Cooper, of

Pellon. I have a child called William, and had one called Benjamin, who is now dead. Last summer William was poorly a few days in the scarlet fever. Mr. T. Fawthrop told me it was scarlet fever. He came to my house to see him for nearly three weeks. I fetched some medicine for him. Mr. Fawthrop told me to go down to his place in the Square for the medicine. I went to his shop, which has a great many bottles in it. Mr. Fawthrop mixed the medicine, which I took home and gave to William. He has sent me a bill, but which I have not yet paid.

Cross-examined.—Mr. Fawthrop has attended three of my children. He attended James, who was very ill, but he recovered and Mr. Fawthrop got him very well through. We only called on Mr. Fawthrop the day before Benjamin died, and we blame ourselves for not sending for him earlier. Somebody has been telling us that we have no occasion to pay him for these services, but I shall pay him as soon as I am able to do so, for he did his best, and I shall not grumble to pay him.

Martha Mansley.—I am the wife of Squire Mansley, of Pellon. Stephen and James Mansley, two of my children, are both dead. Previous to their death, "Dr. Fawthrop" attended them; he saw Stephen twice and James twice. He said they had the scarlet fever. I fetched some physic for them from "Dr. Fawthrop's," in the Square. He made it up, or I saw him do something with it. I took the medicine and gave James some of it. He sent me in a bill. I paid him 8s. 6d., and he gave me a receipt for it.

Cross-examined.—It was a bottle he gave me, and there was a label on it like the one now shown me. My husband went for Mr. Fawthrop, and it was the desire of both of us that he should be sent for. We were quite satisfied with his treatment. "J. Fawthrop and Co." was upon the receipt, and it is also the name over the door.

Mr. E. J. Rudd.—I know Mr. Thos Fawthrop; he lives at No. 1 or 2, Square, and is the tenant of a house for which I am steward. He was first entered on the 7th of Jan., 1850, as a tenant of Sir Charles Ibbetson's. His name was substituted for that of Mr. Joseph Fawthrop at the time to which I allude.

Mr. Job Bentley, Deputy Registrar of Deaths, &c.—The two papers I hold in my hand are medical certificates of the cause of death.

Cross-examined.—I did not see the certificates written. I receive certificates of the cause of death in every case. They are frequently signed by assistants, on behalf of the principle.

Mr. T. Harrison, surgeon.—I know Mr. Thos. Fawthrop, and have seen him write more than once. The signatures upon the two certificates of death shown me are the writing of Mr. Thos. Fawthrop. The writing upon the bills sent to Mansley and Cooper is that of Mr. Thos. Fawthrop.

Cross-examined.—I have been subpœnaed to attend this day. I have said that Mr. Fawthrop was a quack doctor, but I never said I would shut him up his shop, or that I would put him a spoke in his wheel. It is not one of my expressions. I have employed him to visit my own patients, and have committed patients to his medical attention for days together. I did not know that Mr. Fawthrop was apprenticed to his father before I came to Halifax. [Mr. Wavell was proceeding to put in a number of certificates, &c., but they were objected to by the Judge.] For months together Mr. Fawthrop attended to my patients. I have not been busy in getting up this action, and have nothing to do with it. I have a senior apprentice who compounds medicine for me. During the long illness of the late Mr. Jubb, Mr. Smith attended to most of his patients. Mr. Stocks attended to some.

Re-examined.—I have not seen the passing certificate among the certificates shown me by Mr. Wavell.

Mr. Wavell submitted that no case had been made out, inasmuch as, the statute being a penal one and the proceedings being in the form of an indictment, his friend had not fixed the day of the offence. The indictment charged the defendant with practising as an apothecary on the 1st day of July, 1850. He submitted that the rules of the law ought to be strictly observed in this case, and that no offence had been proved against the defendant on the 1st day of July.

His Honour over-ruled the objection; as the witness Morley stated that his father died on the 9th of July, and that the defendant was fetched to him 16 days prior to that time. The point, however, should go to the jury.

Mr. Wavell then submitted that there was no case to go to the jury, inasmuch as the plaintiff's own evidence proved that the bill sent in was to *Mrs.* Morley, for medicine and attendance; whereas it ought to have been made out to the executors of the late Mr. Morley. (This point was also over-ruled.) He then submitted, with greater confidence, that everything charged against Mr. Fawthrop was perfectly consistent with the Act of Parliament. It was shown by the evidence called for the prosecution that it was a common practice for assistants to compound medicines and to visit patients; and the 17th sec. of the act exempted the persons then acting as assistants or who had served an apprenticeship of 5 years to an apothecary. (This objection was also over-ruled, as the exemption applied only to persons *then* practising when the act came into force.) Mr. Wavell then proceeded to address the jury, dwelling mainly upon the points which he had previously raised. The act under which the penalty was sought to be recovered had now become an almost obsolete statute. It was passed in 1815,—in that year of trouble and distress, consequent upon the ending of the northern war,—and was not intended to apply to the visiting of patients but to the mixing and compounding of medicines. The receiving and compounding of a physician's prescription by any druggist in Halifax was, therefore, an offence against this act, unless he was a member of this college. The absurdity of such a proceeding was this,—a man may lawfully visit and advise his patients, may practise as a midwife and attend all cases of parturition, but, the moment he began to mix a rhubarb pill, or a little senna with something else, in came the statute and imposed a penalty of £20. Would such a state of things be tolerated in a free country like this? The statute had not been extended to Scotland or Ireland, but only to England; and the public had invariably refused to execute its powers. He argued, at some length, that the present case was not contemplated by the statute. Mr. Fawthrop was the son of a medical

gentleman of 40 years' standing in this town; he had served an apprenticeship of five years with his father, and afterwards served some time as a dresser in the Halifax Infirmary, where he received a most flattering testimonial; he had also a multitude of similar testimonials from other infirmaries and hospitals, and from some of the most eminent practitioners in Europe. At the time of his father's death Mr. Fawthrop was in London, and by the wish of his brother,—Mr. J. Fawthrop, a surgeon of extensive practice at Queenshead,—he came down to Halifax, and arrangements were made for his commencing practice as an assistant to his brother. As such he had continued to practise, and everything proved to have been done had not been done by Thos. Fawthrop, but by J. Fawthrop and Co. It was, therefore, strictly incumbent upon his friend to have shown that the defendant was not an assistant. After some further observations, the following witnesses were examined:—

Ellen Sutcliffe.—I am domestic servant with Mr. Chappel, but was formerly in service at the house of the defendant. I have frequently seen Mr. Joseph Fawthrop at the place. I have seen him in the surgery making up medicine, order about things, and converse with patients. He attended regularly on Wednesdays and Saturdays. Patients came regularly to see him. When I went there was a very old sign over the door, which Mr. Joseph ordered to be taken down and sent to Queenshead; and a new one came in its place. "J. Fawthrop & Co." was written upon the new sign. The same was also put upon the lamp over the door.

Cross-examined.—Mr. Thomas gave me my wages, but I believe Mr. Joseph paid him. I went on the 2nd Jan., '49, and left in the beginning of May the same year.

Jonathan Oldfield.—I am in the employ of Mr. Watson, ironmonger. I was poorly in '49, and called in the Square for advice. I saw Mr. Joseph Fawthrop, who prescribed for me, in the consulting room.

John Foster, glazier.—I fitted up the house in the Square with gas in 1848, by the orders of Mr. Joseph Fawthrop.

Thomas Fawthrop.—I reside at No. 2, in the Square, which is the same house in which my father lived, and where I served a five years' apprenticeship. I served four years as dresser at the Halifax Infirmary. (a number of certificates signed by some of the most eminent members of the profession were put in, but were designated by Mr. Holroyde "mere painted pictures," and of no value in the present case, inasmuch as *the* certificate was not found amongst them.) I kept an open surgery in London at the time of my father's death. Two years after my father's death I came to reside at Halifax. This was in December '48. Mr. Joseph Fawthrop, my brother, and who has practised as a surgeon at Queenshead for a considerable period, fitted up the surgery. I have resided in the Square since that period. Along with my brother I have visited patients. During this period I have been frequently applied to by other surgeons to attend to their cases. "J. Fawthrop and Co." is over the door. I was an assistant to my brother up to the 10th of August last. The letter I produce was written by my brother. (A passage was read from this letter, dated October 21, '48, authorising the use of the name "J. Fawthrop & Co.") The arrangement has not yet been a lucrative and profitable one. The expenses and living exceed the income. It is by my brother's authority that the sign is there.

Cross-examined.—The letter I produce is a letter to "my dear sister and brother. The "sister" is my wife. I am sure she is my wife, and I am sure we are married. This letter is part of the authority under which I act. (Mr. Holroyde read the letter partly through, and his Honour the remainder. Another letter, dated September, 1848, was also read.) I went for examination to the Apothecaries' Hall, and was rejected. I applied again, and again failed. I did not go a third time. The second time I went up was in 1842. I live in the Square, and am tenant of the house. Mr. Joseph Fawthrop does not live there. It is nine or twelve months since Mr. J. Fawthrop was there. I acted under him until the 10th of August last. My brother has not slept in the Square since I came to Halifax. The printed paper produced (an address to the public) was printed about January, 1849. I got it printed. The sign now is "J. Fawthrop and Co." There is on the door, in addition, "Pearce, Surgeon." Mr. Pearce has been with me since August. I act under him.

By the JUDGE.—The terms agreed upon between me and my brother were, that I was to act under him. No agreement as to the profits was made. My brother did not require the profits. No arrangement was made as to my having a salary, or otherwise. I had no communication with my brother at the time of my attending the cases before mentioned by the witnesses.

Mr. HOLROYDE, in his reply, commented upon the objections or quibbles raised by the defendant, and said his friend had failed to show that the Act of Parliament had been complied with, inasmuch as he had produced no certificate of Mr. Fawthrop having passed the College, showing that he was duly qualified to act as an apothecary. Supposing he had been an assistant to his brother, (which he denied,) even that would not have been sufficient, because of his brother residing at Queenshead. The law contemplated that where an assistant was employed, the public should at all times have the benefit of the skill and advice of the principal, who should not reside at a distance, but upon the spot. He should now call Mr. J. Fawthrop, and then leave the case with the jury.

Mr. Joseph Fawthrop.—I am a surgeon residing at Queenshead. My brother Thomas was never an assistant of mine, nor a partner either.

His HONOUR said the question for the jury to decide was, whether the defendant had practised as an apothecary without having obtained a certificate. He then proceeded to read over and comment upon the evidence, and with regard to the last point raised by Mr. Holroyde, said that it was his opinion that where an assistant was employed, the principal ought to reside upon the premises, so that his advice could be at all times available by the public. He should wish the jury, in deciding upon their verdict, to say—1st, whether the defendant had acted generally as an apothecary without certificate; and, secondly, whether he did so act on the 1st of July.

The jury retired for a short time to consider upon their verdict, and upon their return into court the foreman said they found a verdict for the plaintiffs.

By the JUDGE.—Do you find that the defendant was practising as an apothecary on the 1st of July.

The Foreman.—We find that the defendant was practising on the 1st of July, and that he was not acting as the assistant of his brother.

Mr. FOSTER (in the absence of Mr. Wavell) requested that the penalty of £20 might be paid after the rate of £1 per month. An order was, however, made for £2 per month.—*Halifax Guardian.*

Correspondence.

STRANGULATED HERNIA, COMPLICATED WITH RETAINED TESTIS.

To the Editor of the Provincial Medical and Surgical Journal.

SIR,—The remarkable nature of the subjoined case of strangulated hernia within the inguinal canal, terminating fatally, and the dilemma in which an operator in a similar case might in future be placed, are circumstances creating, I believe, a sufficient interest to make the following facts worthy of record in your journal. Should you also be of the same opinion, I shall feel obliged by your giving the paper a place in an early number. I remain, Sir,

Very truly yours,
E. A. TURLEY, M.D.

Ivy House, Worcester, Feb. 3, 1851.

On the 1st of February, 1851, I was called at six A.M. to attend Mr. H——, of Worcester, a hale but rather spare man, aged 78. He was in bed, breathing hurriedly, with a pale anxious countenance and faltering voice, occasionally interrupted by hiccough. I observed by his side a vessel containing about a pint of thin fluid, resembling muddy coffee, which he said he frequently rejected since Wednesday (three days); and that since that day he had had no relief by the bowels. I inquired if he had a rupture. He said nothing had come down, but that he had had pain in the right groin ever since sneezing violently at noon on Wednesday. I found a small hardish tumour in the inguinal region, which gave him pain on pressure. Examining the scrotum, I discovered no testis on the right side; a fact, he told me, of which he had been always conscious. I then suspected he had congenital hernia, and erroneously supposed this strictured at the upper ring of the inguinal canal. I moderately attempted to rectify this supposed condition by gently forcing up the tumour. This produced great pain, and I desisted, and informed my patient that I believed an operation would afford him the only chance of recovery; and proposed a consultation. He stoutly refused to submit, and determined to meet his fate. Having informed his family of their father's condition, I gave him an opiate, and left him. In three hours time I found him worse; and he died fourteen hours after I first saw him. Mr. Meears assisted in the necroscopy sixteen hours afterwards. We made a dissection of the inguinal region, and found the inferior opening of the inguinal canal partially closed by a blighted or hypertrophied testis of the size and form of a plum stone, accompanied by an epididymis of disproportionate largeness. It lay just within the external ring, on a bed of cellular tissue enveloping the spermatic veins and the vas deferens, though this soon became indistinct in its ascent towards the os pubis. A pouch apparently of the size and form of a horse chesnut was attached to the upper part of the dimunitive testis, containing a portion of the ileum strongly strictured by some fibres of the transversalis muscle, which seemed to have formed a tight band, surrounding the intestine within the inguinal canal,* the upper opening being sufficiently patent to have allowed the re-ascent of the protruded intestine. The strangulated portion of the gut appeared gangrenous.

Remarks.—The facts revealed on dissection would have rendered an operation nugatory; nor did the state of the patient on my first seeing him invite such a step. Earlier in the case an operation might have been successful, though much embarrassment would probably have occurred by so anomalous a condition of the parts. I am not acquainted with any exactly similar case on record, though the late Mr. Key's memoir is quoted from in Mr. South's excellent surgical work, volume 2, page 62, and a reference is also made in an adjoining paragraph on the same page, by Mr. South, to a congenital rupture in the inguinal canal, the preparation of which is in the pathological museum of St. Bartholomew's Theatre of Anatomy.

Whilst my pen is in hand I will relate another case of a testis retained in the inguinal canal, in a commercial traveller. Mr. L. applied to me in May, 1837, and exhibited a large inflamed tumour in the right inguinal region. It was exceedingly tender and painful, and excited frequent retching. It had existed, he said, two days; and here I also found the right hemisphere of the scrotum empty; this he had never noticed. He said he had been suffering from gonorrhœa about a fortnight, but that the discharge had ceased the day before the tumour had made its appearance. Leeches, the warm bath, and aperients, with a night opiate and entire rest, constituted the treatment, which lasted the usual time necessary for the cure of hernia humoralis. Some cases are recorded by Sir A. Cooper and others of retained testes performing their functions equally well in their pristine position; and the patient first named had been the father of a large family.

E. A. T.

* See Sir A. Cooper's work on the testis, plate 5.

Medical Intelligence.

THE FELLOWSHIP.

The following are correct copies of the questions submitted to the candidates who presented themselves for examination for this distinction, on Monday, the 7th instant:—

ANATOMY AND PHYSIOLOGY.

1. Describe the structure of the wrist-joint. State what tendons, vessels, and nerves cross the joint on the palmar aspect; describe their position and relative situations.

2. Describe the duodenum, specifying its situation, course, and relations; its component structures and the sources of its blood-vessels and nerves.

3. Describe the course and relative situation of the subclavian and axillary arteries on the right side; mention the branches given off by them; state by what parts the subclavian, external to the scalenus, is covered.

4. Enumerate the blood-vessels and nerves proceeding to the lower extremity, and describe their relative situations and connections at their exit from the pelvis.

5. Describe the vessels and nerves of the orbit, the sources whence they are derived, the apertures through which they enter the orbit, and their distribution.

6. Describe the position and relative situation of the viscera contained in the female pelvis, the peritoneal reflections and ligaments by which they are supported.

PATHOLOGY AND SURGERY.

1. Give the diagnosis of tumours of the female breast dependent on chronic inflammation, chronic mammary tumour, and scirrhus.

2. Explain the leading rules of practice in the treatment of traumatic gangrene, and gangrena senilis.

3. What are the consequences to be apprehended when retention of urine dependent on stricture in the urethra, is not relieved? Describe the treatment suited to its various stages, whether by the use of instruments or other means.

4. Describe the circumstances under which the application of the trephine may be required after an injury to the skull by violence.

5. What are the dangers which attend incised wounds of the throat? Describe the treatment of these wounds.

6. When the posterior tibial artery, where covered by the muscles of the calf, has been recently wounded, what treatment must you adopt? And if there were secondary hæmorrhage and the parts in a diseased state, what practice would you follow?

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted members on the 4th inst.:—Harris Carr Brackyn, Dublin; Henry Walter Bucknill, Rugby, Warwickshire; Thomas Hobbes Cresswell, Folkestone, Kent; William Davey Haye, Callington, Cornwall; George Jonathan Mitchinson, Carrington, Lincolnshire; Julius Grainger Russell, Dudley, Worcestershire; George William Sanderson, Canada; Henry Seatle, Ulverston, Lancashire; Isaac Shortland Shillingford, Greenwich; Stephen John Frederick Stafford, Northfleet, Kent; Messrs. Edward Sullivan, Dublin; John Wise Tracy, Acacia Road, St. John's Wood; Edmund Sydney Wason, Colmonell, Ayrshire.

SOCIETY OF APOTHECARIES.

Gentlemen admitted members on Thursday, March 27th, 1851:—Geo. Dawson Armstrong, Cumberland; Henry Duncalfe, Walsall; John Ewens, Axminster, Devon; William Pilkington, Leyland, Lancashire; Robert Vaile Skinner, Headcorn, Kent; Henry Benj. Wood, New Romney, Kent.

Gentlemen admitted members on the 3rd inst.:—Thomas Abbey Bottomley, Huddersfield; Aynott John James Chitty, Mere, Wilts; Thomas Fuller, Brighton; William Henry Gatty. Market Harboro'; Osborne Johnson, Beckington, Lincolnshire; Samuel Wall Jones, Ludlow, Salop; Henry Maund, Bromsgrove; Edward Mercer, Uxbridge; Frederick John Money, Offham, Kent; William Morris, Petworth, Sussex; George William Nicholls, Darwen, Lancashire; John Daniel Ranson, St. Ives, Hunts; Frederick Moore Smith, Great Hadham, Herts; Francis Cornelius Webb, East Stonehouse, Devon.

BOOKS RECEIVED FOR REVIEW.

A Practical Treatise on the Diseases of the Urinary and Generative Organs (in both sexes). By Wm. Acton, late Surgeon to the Islington Dispensary, &c. Second Edition. London: J. Churchill, 1851. pp. 693.

Urinary Deposits; their Diagnosis, Pathology, and Therapeutical Indications. By Golding Bird, A.M., M.D., F.R.S., F.L.S., &c. &c. Third Edition. London: J. Churchill, 1831. pp. 328.

Pharmacopœia Collegii Regalis Medicorum, Londinensis: J. Churchill, 1851. pp. 196.

Translation of the Pharmacopœia Londinensis. By a Physician. London: H. Renshaw, 1851. pp. 226.

Phthisis and the Stethoscope. By Richard Payne Cotton, M.D., Assistant Physician to the Hospital for Consumption and Diseases of the Chest. London: J. Churchill, 1851. pp. 97.

Dr. Warren's Address before the American Medical Association at Cincinnati. Boston, 1850. pp. 65.

An Essay explanatory of the Tempest Prognosticator. By George Merryweather, M.D. London: John Churchill. 1851. Pamphlet; pp. 63.

The Journal of Psychological Medicine. April, 1851.

Monthly Journal of Medical Science. April, 1851.

London Journal of Medicine. April, 1851.

The Medical Examiner. Philadelphia, Feb., 1851.

The American Journal of Dental Medicine. Jan., 1851.

Religion and Science. By a Physician. Pamphlet.

A Letter to the Right Honourable Lord Campbell, on the clause respecting Chloroform in the proposed Prevention of Offences Bill. By John Snow, M.D., Licentiate of the Royal College of Physicians, &c. London: J. Churchill. 1851. Pamphlet. pp. 16.

The London Journal of Medicine, March.

The Medical Examiner, November and December, 1850—January, 1851.

Monthly Journal of Medical Science, March.

The American Journal of Dental Science, July and October, 1850.

A Letter to the Right Honourable Sir George Grey, Bart., M.P., on Medical Registration and the present condition of the Medical Corporations. By Emeritus. London: William Tyler, Bolt Court. 1851. Pamphlet.

TO CORRESPONDENTS.

Communications have been received from Dr. Nelson, Mr. Deane, Mr. Harvey, Dr. Edwards, A Member of the Provincial Medical and Surgical Association, Dr. Little, Mr. Sleeman, Mr. Millar, and Dr. Norris.

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho. But all communications respecting the routine business of the Association should be forwarded to James P. Sheppard, Esq., the Secretary of the Association.

It is also particularly requested that all post-office orders should be sent either to the Treasurer or Secretary, who alone have the power of giving receipts.

CLINICAL LECTURES

ON THE

PRACTICE OF PHYSIC,

DELIVERED IN THE

THEATRE OF QUEEN'S COLLEGE, BIRMINGHAM, 1849-50.

By DAVID NELSON, M.D.,

Physician to the Queen's Hospital, and Professor of Clinical Medicine, &c.

[Reported by MR. WILLIAM ROGER BANKS, Student of the College and Clinical Clerk.]

LECTURE IV.

Morbid Conditions of the Brain, &c., (Continued and concluded.)

The next morbid condition to be reviewed, is that of paralysis: as spasm and convulsion consist of a perverted action of the nervous powers, so paralysis is a loss of them—total or partial, as the case may be. According to the synthetical principles already announced, I shall not treat separately of those numerous nosological subdivisions of this malady, known under the names of universal paralysis, paraplegia, hemiplegia, &c., &c., but shall only speak of paralysis in its one pathological sense—of a suppression of nervous force, extending, it may be, over the whole body, or limited to one muscle, or amounting merely to diminution of power, or else its total annihilation. The various causes of this particular condition come under a separate catagory. It may arise from agencies operating directly on the cerebro-spinal centres themselves, such as a violent shock, or any solid or fluid pressure thereon, or the presence of hyperæmia, and its different consequences. If these involve both sides of those centres, then the paralysis will be complete; but if they only occupy one side, then the opposite side only of the body will be affected, or if they only occupy the upper or the lower part of the chain, then the upper or the lower part of the body will be respectively prostrated. It may likewise happen that the nerves of sensation only will be affected, or on the other hand only the nerves of motion, and I once witnessed a case in the Royal Infirmary, Edinburgh, about twenty years ago, under Mr. Liston, where one limb had lost its motion and the other its sensation. The patient was a painter or glazier, who had fallen from a height across the street rails.

One very important point of inquiry in this malady is, whether the lesion has primarily commenced in the nervous centres, or at their periphery, for upon this depends the line of treatment that ought to be pursued. When it takes place suddenly, without any apparent external cause, or when it is of considerable extent from the beginning, we may safely infer that the origin is central. On the other hand, if it gradually ascend from any extreme point of the body, and more especially, if we observe that some deadening influence has been applied to the part, such as intense heat or cold, or any irritant that has or has not excited inflammation; or, if the paralysis be markedly limited, in that case, we may fairly view it as peripheral. This peripheral affection of the nerves may be simply local, and therefore removable by the appropriate remedies. But it may also be universal, commencing in the extreme points of all the extremities at once, and gradually creeping inward until the whole frame is involved, and the mental faculties ultimately obliterated. This is general paralysis. Yet we are not always to conclude that because the symptoms of this disease have first made themselves manifest at the pheriphery, that the morbid action must necessarily have begun there. On the contrary, there may be many preceding appearances, which shall rather incline us to conclude that it has sprung from the centres. Before diseases of the heart were understood as they are now, several affections of the ultimate parts of the circulating system, such as dropsy, and congestions of the liver, kidney, lungs, &c., were wont to be viewed as primary lesions of those parts, instead of being referred to a morbid condition of the master organ. Now that attention is especially directed towards that organ, which, with the exception of its innervation, is altogether a purely mechanical device, matters are cleared up with a surprising simplicity. But the cerebro-spinal centres are much less easily understood, and hence the difficulty that besets the one question as compared with the other. No doubt we may observe a paralysis, commencing extensively at the periphery of the nervous system, independently of any discoverable external cause, while the brain and more central parts are apparently in full vigour. Thus, in that form of gangrene, (whether occurring in old age or not,) which is commonly traced to the ossification of the arteries, (though in the case of Thomas it seemed rather due to an universal oily degeneration,) we shall have at the commencement, a simple loss of sensation and motion at the points of the extremities, bearing the strict character of a peripheral paralysis. The affection may most commonly be confined to the lower limbs, but we can have no difficulty, for argument sake, to suppose that it should in one given case, arise simultaneously at every extreme point of the body. The result would be a gradual inward march of the disease, with local death following in its wake, so that the centres would be the very last to suffer any inconvenience. Indeed, life would be extinct from secondary causes before the specific action had time to reach them. But, although in such an extreme case, it might be averred that this was peripheral paralysis, arising from an internal cause, yet it is to be remembered that the internal cause is not a nervous one, and is therefore to be viewed in a pathological sense as an external cause—external, that is to say, to the nervous system, as one whole and united tissue, as much as a tumour, or the exudation of an inflammation, &c, would be, while pressing on any one of its chords. From these considerations, therefore, I am firmly of opinion, that, except we can trace the direct local influence of foreign matters, or an absence of the natural nutrition, we are not justified in viewing an universal peripheral paralysis as anything else than a symptom of certain lesions that have befallen the nervous centres themselves. In short, if we cannot

demonstrate any change of anatomical structure in the peripheral nerves, or in the conditions under which they should act, we are not entitled to consider the disease as other than a functional one; and, if functional, then we must look to the source of the function for an explanation. This is of prime importance as a matter of practice; although, perhaps, the safest course to pursue is to treat every case under the impression that the centres *may be* affected, and so seize the likelihood of doing good, without any probability of doing harm. This may seem an empirical precept; but it is the duty of the physician to look to the safety of his patient rather than to any pragmatical exercise of his own theories in matters of such difficult solution. Above all, if we feel certain that a disorder is referable to, at most, two causes, though not with certainty to either the one or the other, we must at once act so as to meet both suppositions, and not suffer the patient to die while we are weakly deliberating, or rather trifling between the horns of a dilemma.

Partial paralysis may occur from sundry local causes; in one or more fingers, or in a hand, or limb, or in the tongue and muscles of the cheek, &c., &c. Not an unfrequent cause of these forms of the affection is exposure to cold, such as draughts of winter air blowing for so long a period on any part of the body as to benumb it. Another cause is the immersion of a limb or limbs for a long time in cold water. They also frequently result from rheumatic inflammation, either affecting the fibrous sheaths of the nerves themselves, or pouring out its exudations on the surrounding tissues, as in the cases of Hannah Wortley, Sabill, &c., &c. When one entire half of the body is involved, (hemiplegia,) we are to refer it in general to a primary cerebral affection, in which case we shall commonly find the head referred to as a seat of uneasiness, or else some obscuration of the mental faculties, as in the cases of Caroline Phipps, Mary Sanders, John Barnett, and Sarah Steele, all of whom recovered. If the lower half of the body only be affected, (paraplegia,) of course we must trace it to some lesion in the lower part of the spinal chord, whether it be an idiopathic affection, or a reflection of irritation from some such important organ as the uterus, kidney, bladder, or testicle. When the entire frame is utterly helpless, we are then to attribute the evil, in sudden cases, most certainly, and even in gradual cases, very probably, to an affection of the brain.

In viewing this affection as one of a purely idiopathic nervous origin, I leave out of consideration those mechanical causes which have already been considered under other heads, such as blows, and effusions of blood or serum, simply pressing on the brain, &c., and arresting their functions while otherwise healthy. In such cases paralysis, whether partial or general, is rather to be viewed as a secondary consequence, and I now speak of it more as a disease *per se*, proceeding from some morbid action originating in the nervous tissues themselves, and ultimately leading to their degeneration. Of such kind is hyperæmia, whether arterial or venous, and also those vitiations of the nutritive processes which are known as scrofula and cancer. In this manner, after death, the nervous centres may be found hardened, or softened, or enlarged, or atrophied, by such processes, or also so replaced in certain parts by other structures, that no portion of the natural fabric is found to exist. In such cases it might be considered that the paralysis should always be gradual, and never sudden; but it is to be recollected, that much devastation may go forward in such organs without any very apparent effect, until the last degree of injury is inflicted. The nervous chords, &c., may be, in some manner, compared to electric wires, which will continue to act, while yet the slenderest filament of metal can permit the passage of the subtle influence, but that being at length broken, all communication must suddenly cease. So is it with the brain and nerves. One unbroken tube may be the means of preserving some sort of intercommunication between the powers of the will and the executive nerves, so that, as we have already shown by the citation of cases under other heads, disorganization within the brain may go on to a very serious extent, without any alarming symptoms being produced, until some remaining structure is attacked, which at once produces the fatal lesion. So the paralytic affection, by which I strictly mean the loosening or weakening of function, from causes confined to the organ of the function itself, may be limited to the cerebral hemispheres, leading to partial or total fatuity, yet with perfect bodily motion; or it may be confined to the spinal system, with a loss of bodily motion, and a tolerable or even a full possession of the mental faculties; or it may seize more immediately on that intermediate chain which I have called the digestive track, and which, from the nature of its functions in the lungs, heart, and stomach, must speedily lead to the abolition of everything else. Or paralysis may be limited to a part, or extended over the whole of the ganglionic system, in which case the danger will be slight, or extreme, according to the extent or portion of that system affected; for sometimes there is a general sluggishness of these organic filaments, while at others there may be a special paralysis of the ganglia of the bowels, or of the kidneys, or of the heart itself, which last must be soon fatal. Such is the result of several sedative poisons, such as hydrocyanic acid, digitalis, and the like. In that utterly fatal form of the disease called, by speciality, general paralysis, we have a consentaneous gradual reduction of all these several faculties, as, firstly, a general languor of the body, and torpidity of the bowels, &c.; also a dragging or tottering of the limbs, and an obscuration of intellect and feeling, slowly, yet certainly, advancing to complete loss of muscular power; utter fatuity, and general wasting of the tissues, until at length the medulla oblongata is stopped in its functions, and all that remained of human life, namely, respiration and circulation, are at an end.

Of these several forms, those which arise decidedly from local or temporary causes, or which are limited to the tongue, or a few fingers, or one limb, are the least dangerous; yet all of them are to be viewed in a very serious light, as it is very seldom that any one of them

will take place without ulterior consequences of a more alarming description. They ought, also, to be treated at once in a vigorous and decided manner, as after nine or twelve month's standing, they are to be looked upon as nearly incurable. There will be the more reason for this decided treatment if there be any want of clearness of intellect, or any dilatation of one pupil compared with the other, as indicating a failure in the central organ. We have seen this exemplified in sending cases here, which will be specially commented upon at another period of the course. Next to the slighter affections above mentioned, those of the inferior extremities will be generally found to be less serious, and more tractable, than those of the upper; and it is no uncommon matter in hemiplegia to restore, in a great measure, the powers of the leg, while those of the arm remain in abeyance. This was well illustrated in the cases of Caroline Phipps, George Rogers, and several others.

The treatment, as may be inferred from the foregoing observations, will be modified according to the form and degree of the disease. When it proceeds as a secondary result from direct shock, or pressure on the brain, we must pursue the measures already directed under apoplexy and other heads; but where it arises from a diseased action specially appertaining to the neural tissues, we have to consider the nature of that action and its situation. If confined to a portion of the periphery only, and clearly traceable to local agencies, as compression, or hyperœmia, or loss of nutriment, our attention may be simply directed to the part, while we see that the general health is in good condition. Compression is to be met by discutient treatment, such as iodide of potassium, preceded by mercury, along with resolvent liniments, and bathing in hot water. This latter expedient you have seen resorted to in many cases of local swellings about the joints, producing paralysis. It softens the tissues, and not only permits the joints to be freely bent, and so relieved from permanent stiffness, but also promotes absorption. The blacksmith, Phillips, who had his right arm bent and useless in this way, from being suffered to carry it in a sling while labouring under fibrinous rheumatism, had the powers of it quite restored in a great measure, by this simple remedy. It is here to be observed, that before any such remedies can act well, some local abstraction of blood may be necessary in order to unload the vascular passages, and allow of free absorption. It may be also remarked that iodide of potassium will always act more speedily if the adventitious tissue be first a little softened by such an amount of mercury as may barely affect the gums. The hot water bath, as just observed, is also a powerful auxiliary under such circumstances, as while it softens the tissues, it enables the limb to be freely bent upon its joints, thus avoiding the evil of a permanent stiffness. If there be an inflammation of the nerve itself, it will, most likely, be of a rheumatic character, and limited to the fibrous lining, in which event, mercury and colchicum will be advisable, with such adjuncts as you will see under the head of rheumatism. If there be want of nutriment to the part by reason of any obstruction to the flow of blood, stimulant frictions must be employed, or a succession of blisters to the tenderest places, along with such tonics as augment the force of the general circulation, as iron, zinc, or arsenic. Zinc was employed in Phipps' case, and arsenic in Sanders', both with equal effect; but no one remedy will act in any specific manner in all cases.

When paraplegia occurs, we must carefully endeavour to decide whether it is from a primary affection of the chord itself, or from a reflected irritation, proceeding from some of the viscera lately alluded to. With this view, we must particularly ascertain the condition of the kidneys, ureters, bladder, and urethra; also of the uterus, ovaries, or testicles, and treat these if necessary; but if these be sound, we can only endeavour to stimulate the limbs, while we apply the counter-irritation of a seton, or of potassa fusa, or the actual cautery over the part of the spine most probably diseased. All this, however, will too frequently be of no avail, and while you bring your patient to the most perfect condition as to general health, so that he looks hale, strong, and ruddy, his lower limbs will still refuse their office, and remain for a series of years perfectly useless. Thus in the case of Green, a bargeman, who first had syphilis, next caught cold from working in the wet, while under mercury, and lastly, strained his back by endeavouring to lift a very great weight, we restored him to all the appearance of rude health, both as to bulk of limbs and complexion, and yet, in spite of purging, tonics, frictions, issues, and every other divisable expedient, he cannot rise without the greatest effort and uneasiness, and only crawls about upon crutches.

Hemiphlegia affords us pretty decided evidence of a cerebral affection, and, therefore, in that case, we direct our treatment still more decidedly to the head. While we regulate the general health, and administer metallic tonics, we maintain an issue for some time behind the neck. Under this treatment, if not too confirmed, we may either succeed in restoring the entire powers, or else improving the lower limb, while the upper one is unchanged. We may even maintain a seton for some time over the brachial plexus, without any visible change. This latter device was practised on Caroline Phipps, but with no beneficial result. In other cases the seton behind the neck has proved the chief apparent cause of improvement, both in the lower limbs and body generally, as in John Barrett, Mary Steele, &c.

When universal paralysis suddenly supervenes in a plethoric habit, general blood-letting may prove of signal service, followed up by smart purgation; but if the habit be spare, more good is likely to be effected by a seton long continued, as well as peripheral stimulants, and attention to the general health. When this dreadful disease is of slow progress, it is surprising how many symptoms upon symptoms will be passed over as trifling by the victim and his friends. A shuffling, tottering, or dragging gait, torpid bowels, a thick speech, a confused indifferent mind, will, like the gradual advances of insanity, be all treated as things of little moment; until the disorder reaches such a length as to startle the observer, and the physician is called in when too late, as in the case of Edward Yates, which I shall soon

describe. Nay, among certain people the above incipient warnings, so far from exciting sympathy, will merely elicit a strong suspicion that the victim of real disease is the victim of his own vices. Drunkenness and other exhausting evil habits are, no doubt, very frequent causes of this malady; but it may also be induced by over-anxiety, and excessive mental exertion under distress and the infirmities of age, as exemplified in the memorable example of Sir Walter Scott, and many others. A most melancholy catalogue, well calculated to humble the pride of human intellect.

While this disease is yet in its early stage, and the age and general condition of body leave hope of recovery, our reliance must again be upon setons behind the neck, and warm tonic aperients, such as a combination of zinc or iron, with aloes or capsicum. The constitution, under such circumstances, cannot bear heroic treatment, and thus the only means left is to institute a drain as near the seat of disease as possible, and maintain the general strength by medicines such as the above.

Should any of these paralytic states arise from the presence of tubular or cancerous deposits, as might be inferred from the general aspect and history of the patient, other additional steps might be necessary. In the former case I should feel inclined to depend chiefly upon a course of cod-liver oil and phosphate of iron; and in the latter, while, not adventuring to give any opinion whatever, I should certainly adopt the use of the iodide of arsenic. Except under mere torpor or exhaustion of the spinal system, I do not think it can be said that strychnia has proved of much use in these cases of paralysis. For illustration of complete cases or individual symptoms, such as have above been alluded to, you can peruse the cases of Green, Bayley, Sanders, Phipps, Thomas, Fisher, Faulkner, Adams, Sabile, &c., as recorded in the ward-books; but more especially I would now submit to your attention three very marked instances of head disease which have recently occurred. These are peculiarly interesting, from the circumstances under which two of them have recovered and one died; the former two being young, and early under treatment, while the latter was old, and not placed under us till the malady had been upon him two months.

The case that first presented itself was that of John Barratt, a young man, aged 34. The history given was, that on the morning previous to admission he had got out of bed, but forthwith fell down, and was put back again. A second time he made an effort to rise, but once more fell, and, on being again placed in bed, he soon lapsed into a state of stupor and utter immobility. When he was brought to the hospital he was quite comatose, and incapable of any motion, each limb falling down like a log as soon as it was raised and left to itself. Under these circumstances he was leeched behind the ears, had his head shaved and cold water applied, and was placed under mercury coupled with purgation. A seton was likewise inserted at the nape of the neck. After a certain time he recovered from the coma, but still laboured under a heavy degree of stupor. At first he could not speak at all, though by-and-by he began faintly to say "yes" to everything. Then it was found that complete hemiplegia existed on the right side, though the left was unaffected; and when he was desired to show his tongue, he would, after much trouble, raise his left hand and draw it forth. This state of things continued for a considerable time, and there was a settled fear in our minds that the matter would end fatally within a longer or shorter period. However, by perseverance in the above measures (the mercury never yet affecting him physiologically, though he took two grains of calomel every sixth hour), he at length began, in a very gradual manner, to regain the use of the right side, while his understanding also improved. When he was so far well as to get up and move about, the above treatment was stopped, and he was put under a course of the phosphate of iron. Now he is remarkably stout, and eats and sleeps well, but the powers of his right arm are imperfect, and he drags his right leg in walking; while his mental faculties are dull to a degree best expressed by the Scottish word "doited."

The second case is that of Edward Yates, a respectable head gardener, somewhat advanced in years, and who had evidently been a person of considerable judgment and intelligence. Two months before I saw him he had been called up in the night time, in cold weather, to stop the progress of fire in a hay-stack. Under this duty, he was greatly excited both in mind and body, and stated that he had felt as if roasted alive. After he had done, and got home, he shivered to a great degree, and was much disturbed by dreams during the remainder of the night. Next morning, on rising, he found that his limbs had lost their natural vigour; but he and his family thought that such a symptom would go off in time. It did not, however, but continued to increase, along with mental dulness, until his employer obtained a hospital note for him. On presenting himself as an out-patient, his manner of entering the room at once indicated the nature of the disease. He advanced straightforward, with a staggering and faltering gait, bending forward at the neck and knees, and the whole body rather inclined to the left side. He did not take off his hat, nor take his seat in the usual place, but drew the chair towards the fire, and sat down as if to smoke. On being addressed, he gave intelligent answers, but forthwith wandered from the subjects, and seemed to forget them. On being told to show his tongue, he thrust it out, and kept it in the same position until he was told once or twice to draw it in again. In like manner, when he was told to exhibit his walking and the motions of his extremities, he would persevere in going on with the exercise until he was actually stopped by physical means. Being liable to stumble and fall, he was led by friends to and from the hospital; and while, in the meantime, he had a seton placed in his neck, and was subjected to purgation, he was advised to become an in-patient. As an in-patient he suffered many alternations during a space of two months and upwards. At first he seemed gradually to improve, but had first one relapse and then another, in consequence of falling twice with his head against the iron bedstead. After this he would some-

times be going about the ward, though with a dragging gait, eating his meals at table, and chatting with other patients; whilst at other times he would lie drowsily in bed, take notice of nothing, and even pass his evacuations unconsciously. At length he rather suddenly fell into a state of coma, with first the left and then both pupils dilated, in which condition he tranquilly died, without stertorous breathing, or any other notable symptom. After death a great amount of softening was discovered in the posterior part of the right hemisphere, of the consistence of a very thick cream, and of a pinkish colour. Had he been placed under treatment at an earlier period perhaps the result might have been more favourable.

The third case is that of Sarah Steele, whose history much resembles that of Barratt. She fell down, and first lost the use of her tongue, and then that of her whole right side. She had been for some time under treatment in the town, and when she entered the hospital she had a very black tongue, was excessively stupid and hysterical, and had no use of the right side, while her bowels were very costive. She was placed under mercurial purgation, and took draughts of ammonia thrice a day, while a seton was inserted in the neck, and the head was shaved. By perseverance in this course, and the employment of frictions, she can now lift her right arm to the top of her head, walk across the ward with a little support, eats, drinks, and sleeps well, and can carry on conversation with some degree of intelligence.

There are also, as you are aware, certain affections of individual nerves, in which acute pains are felt shooting along their courses, and recurring either at certain intervals, without any obvious cause, or during the exertion of neighbouring muscles. In the former case disturbance appears purely functional, and is most effectually met by mild aperients, and such powerful tonics as quinine, arsenic, or carbonate of iron. Chloroform, also, is now an invaluable remedy, in the form of liniment; whereas other liniments, even of aconite, belladonna, &c., were wont to be ineffectual. In all such affections, ticdoloreux included, a generous diet, and diversion in the open air, will be advisable, as I have seen numerous cases where the agony was always increased after long fasting, or when bleeding, blistering, and the antiphlogistic regime were resorted to. It is otherwise in the second variety, wherein there seems an inflammatory action going on within the nerve or its sheathings, which is much abated by blisterings, followed by belladonna plasters, and accompanied with the use of mercury and colchicum; when subdued, a return may be warded off by continuing for a time the application of a rubefacient plaster. Other pains simulating these attacks have already been treated of under hysteria, and need not be adverted to further in this place.

Such are the principal affections of the brain, and of the ordinary nerves of sensation and motion. Those of the ganglionic system, which govern the functions of organic life, are as yet so obscure in their connections, and so difficult, anatomically speaking, of being examined in the minuteness of their gelatinoid structure, that little light can be thrown upon their exact mode of physiological action, and still less upon their pathological conditions. This is the more to be regretted, as we know at least sufficient of their nature to be convinced that a true and full exposition of their modes of vital operation would do more for the science of medicine than can possibly be expressed. There is scarely anything taken into the body, either in the shape of food, medicine, or poison, that does not react through the agency of that wonderful system, a complete knowledge of which would make us complete physicians indeed; and an unsurpassed glory still awaits that physiologist who shall reveal to us how that untiring and rhythmal excito-motion is begun, and propagated from chain to chain, during a whole life-time, renewing in its rounds all the structures of the body, and casting off their defecation. Such a discovery would provide us with a master-key to all the arcana of physic, which, until then, must remain as arcana; for much as we are indebted to chemistry for establishing the rude alimental conditions and relationships of the materials of nutrition, it quite fails, as yet, in the attempt to explain those complex and specific laws of affinity which are established, and can only exist under the influence of the vital principle.

I shall now conclude by offering a few remarks upon some of the affections of the organs of special sense; such remarks must necessarily be very brief and general, for some of these organs are so complicated, such as the eye and the ear, as to have had large volumes written upon their various ailments. No doubt, as all these numerous forms of disease are reducible to certain modifications of hyperæmia or degeneration, a repetition of like theories and like plans of treatment must take place in almost every chapter of such books, if we except the surgical operations; nevertheless, there are many special niceties connected with the different shapes and seats of disease, which render such books as those of our own Mr. Middlemore very valuable, but into which I cannot pretend to enter, indeed such special niceties have now become the province of distinct classes in the profession, and therefore the physician need only point out the principles on which they are regulated. I refer you for such niceties to the able and laborious treatise of our ophthalmic professor just mentioned; firstly, of the eye, an organ very delicate, and complicated in its structure, and subject to sundry forms of disease, according to the sundry tissues that enter into its composition. Each part, or the whole, may become the seat of inflammation, and each part may also degenerate, according to the nature of its tissue. The inflammations may be of the common character; or they may be syphilitic, or rheumatic, or scrofulous. In the first kind, whether they be situated in one part of the organ or another, we must, without loss of time, proceed to the abstraction of blood, and to the administration of mercury, as the eye is too important and frail an object to be tampered with under any circumstances. Under any suspicion of a specific action, we must further resort to those remedies which are known to be specific in arresting it, and which will be spoken of under the proper heads. Where the

cornea or other exposed surface is affected, and is running into ulceration, lotions of nitrate of silver and sulphate of zinc are very useful. You are also well aware, that when iritis supervenes, it is necessary to apply belladonna, in order to release the inflamed part, and throw it into dilatation, and prevent it from forming permanent adhesions while in a contracted state. In all cases a careful exclusion of the eye from the stimulus of light is highly necessary, as well as such a diet as shall keep down all vehement action in the parts; but the abstraction of blood, and administratien of mercury, are the essential points which must never be omitted, since the least exudation of lymph is liable to damage the perfection of the organ for life. As to degenerations, these may arise from a congenital cachexy, or from poverty of diet, and general living, or from old age. They may be of a scrofulous, or phosphatic, or a cancerous kind, simply functional as regards the optic nerve and its final expansion. Thus the tubercular degeneration may attack the mucous or serous surfaces, and require the use of iodine and cod-liver oil. The phospho-calcareous deposit may appear on the fibrous or tendinous tissues, and demand a generous diet, with muriatic acid, (if it can do any good in such a case); or the aqueous tumour may become milky, so that it may be expedient to let it out, in order to a clearer fresh formation; or a cancerous tumour may fungate from the bottom of the eye, displacing every structure it successively comes in contact with, ultimately to break, and, in spite of all efforts, pour out that fluid which is only to be exhausted by the exhaustion of the system itself. The degenerations of old age are usually beyond the reach of remedies, being frequently fatty, and constituting the arcus senilis.

The ear, like the eye, is also to be assiduously guarded from inflammatory action, as one of the consequences to be apprehended is a permanent deafness. As it is an organ of great sensibility, it generally gives sufficient warning of any ailment, and such pain should be immediately met by a sufficient number of leeches behind the ear, followed by a blister, while mercury is administered internally, and cotton, dipped in oil and laudanum, is applied within the conch. There is a slow but persevering inflammation that sometimes goes on, especially after scarlatina, which proceeds to involve the bones in caries, and ultimately attacking the base of the brain. This deserves special attention, and its approach should be carefully watched under that disease.

Concerning the tongue and palate there are few morbid features worthy of particular observation, except as symptomatic of the condition of other organs, and which are elsewhere taken notice of. Inflammation, however, does occasionally take place in the tongue, requiring similar treatment as in other places, though most commonly such an affection is to be traced to the action of mercury. There may be œdema of the tongue in anæmia, &c., and little ulcerations will sometimes appear, requiring alterative doses of mercury and chalk, with applications of the honey of borax. Cancer of the tongue is the most serious disease that can befal it; this is commonly traceable to local pressure, in connection with the cancerous constitution, and the discussion of it had better be reserved until we come to the morbid conditions of the capillary system, or of the blood and ganglionic innervation.

The nose affords few instances of disease so peculiar as to take a separate place in these lectures; and I shall merely specially notice one chronic affection, which is apt to be exceedingly troublesome and protracted. It is that slow and persistent sub-acute inflammation, which is apt to continue for years and years after an attack of influenza or bronchitis, or any severe affection of the respiratory surface. Its chief and most offensive feature is a profuse secretion of thick yellow mucus, occasionally varied with clots of blood, which is constantly distilling from the nostrils, and soiling a series of handkerchiefs in the day; while a more annoying circumstance is its aptitude to descend backwards while speaking into the throat, and so causing an arrest of the voice, and a disagreeable sense of choking, which can only be obviated by hawking up the matter in a way not very pleasant to observers. This has been often found to resist almost every remedy; but great and marked relief will often be found from the use of calomel, as a snuff, drawn up three or four times a day. It may not be a dangerous, but it is a very disagreeable affection, and any one would feel gratified by its removal. The same treatment will apply to chronic ulcers or scabs, which will frequently resist every other agency; but if a bloody discharge predominate, acetate of lead will prove useful.

I have now finished with the observations and cases illustrative of the chief affections of the head; and it will have been observed that they embrace some of the most important, most sudden, and also most obscure and most fatal diseases to which the body is liable. Before leaving the subject, I shall only once more call your special attention to the fact of their frequently insidious commencement and progress, and entreat you, both for the sake of your own reputations and the safety of your patients, never to view even a seemingly trifling symptom in the head without due seriousness. Let not the ignorant imputation of your making "a mountain of a mole-hill," to use an expressive vulgarism, deter you from a path of duty, which is clear as day to the learned in such matters. I have shown you on what slight and apparently dubious evidences we are enabled, by experience, to build our fatal prognosis; but not, as you will see, with a view to discourage you from resorting to curative measures; but to incite you to be bold and decisive, while yet you yourselves have hope, and the by-standers, in their ignorance, have no fear. In short, the greatest obstruction to all effective treatment is usually to be met with in the comparative inaptitude of the unprofessional attendants to understand the heavy import of such negative symptoms as clouded faculties, impaired mobility, drowsiness, and partial loss of feeling; but you will greatly increase that obstruction if you suffer your moral determination to be impeded by such indifference, and so defer the use of the requisite measures until too late a stage of the disease.

DYSMENORRHŒA,

AND ITS

TREATMENT BY DILATATION OF, AND THE APPLICATION OF CAUSTIC TO, THE UTERINE NECK.

By SAMUEL EDWARDS, M.D.,

Physician-Accoucheur to the Marylebone Institution for Diseases of Women; lately Physician to the Eastern Dispensary of Bath, and to the Bath Ear and Eye Infirmary; and formerly resident Physician to the Edinburgh Lying-in Hospital, &c.

Since the publication of my papers on the above subject in the pages of the *Lancet* for April, 1849, I have received much additional testimony from many professional friends, as well as from personal experience, of the correctness of the pathological statements therein contained, as also of the success attending the treatment recommended in this very painful and most distressing malady—dysmenorrhœa—one which has, hitherto, by the great mass of the profession, been viewed as an evil which could only at their hands receive temporary relief, to return again, with all its attending miseries, at the next periodical occurrence. My attention was at a very early period of my professional life, peculiarly directed to this affection from a case of the most severe character that occurred in the practice of my friend, Mr. Huxtable, of Hackney, and which continued, despite of all the most anxious endeavours of her medical friends, to torment her periodically until her life was jeopardized by her sufferings. The frequent cases I have met with since of this character, receiving none other but palliative treatment, and not having even the radical cure here referred to recommended, if known, induces me still further to lay before the profession some few cases, in the hope that the attention of others may be directed to a line of treatment so beneficial, and so eminently subversive of periodical suffering. It is not my intention to take up time and space by again making any historical reference to part of this treatment, or of entering into pathological minutiæ; it is sufficient now to state that dysmenorrhœa we believe may be always found to depend upon either,—

1st.—A naturally contracted os, or cervix uteri, especially at its os internum.

2nd.—A contracted or strictured condition of the passage through the neck of the uterus, from previous inflammation and ulceration.

3rd.—From inflammatory congestion of the substance and lining membrane of the body or neck of the uterus, and sometimes of both, with or without ulceration, giving rise to temporary obstruction of the passage.

4th.—Obstruction of the passage from tumours, or other morbid growths.*

Subsequent experience has encouraged me in the belief, that if the subjects of dysmenorrhœa are carefully examined, one or other of these causes will be found to exist, as the producer of this painful disease. It will thus be seen that obstruction in one shape or other, is looked upon as an essential condition; but this, those who have inquired into the subject only superficially may be inclined to doubt, for on examining the os and uterine passage in some cases where dysmenorrhœa exists, room has been found to pass a bougie of moderate size. A similar case occurred to myself some months since, the bougie passed readily on my first trial, nevertheless there was a condition of the passage which made me determined to examine immediately before the expected period, on doing which I found it to be congested and swollen, so that the same bougie could not be made to pass, nor yet a much smaller one, without occasioning bleeding and much pain. This was a case referrible to the third cause, and which, by local bleeding, and the subsequent application of caustic and bougies, very quickly recovered. But more of this by-and-by, in detail.

Case 1.—Mrs. C———was first seen by me on April 26, 1849, she is of dark complexion, and leucophlegmatic temperament, aged 32, began to menstruate at 16 years of age, was "regular," with two or three exceptions, up to the age of 28, since which period has been suffering from uterine disorder, and especially from painful menstruation. Within the last few months her general health has failed, so that she was compelled to give up her ordinary occupation. She has been married six years, and during the first two years enjoyed good health; she then became pregnant for the first time, and miscarried at the third month; three months after she again miscarried at about the fifth or sixth week; and, finally, four months afterwards the same again occurred, since which time she has not been pregnant. The first and third miscarriages were attended with a good deal of hæmorrhage, and gave rise to a lengthened period of debility. Prior to and ever since the first miscarriage, she has had more or less pain in the back, and over the hypogastric region, accompanied with leucorrhœal discharge of a glairy character, sometimes of a creamy looking matter, which was occasionally streaked with blood. During the last eighteen months, she suffered from considerable dysmenorrhœa, at some periods worse than at others, and preceded and followed by much "bearing down."

Present state.—April 26, 1849.—Complains of much debility, so that exercise of any kind is irksome; of various dyspeptic symptoms which have existed several months; appetite is fastidious and trifling; tongue pale and flabby, and indented all round with the teeth; bowels sluggish; pulse small and irritable, averaging about 100. The pains in the back and pubic region still existing, and the past "periods" gone by with so much suffering, as to lay her up for several days; the leucorrhœa is trifling, nor has it been perceptibly coloured for some months. The womb, by examination, is found larger and heavier than usual; the cervix swollen and soft, of a blueish hue, as seen through the speculum, and is in a varicose condition; it presents in two places patches, resembling cicatrices of a recent excoriation. The os is oval, surrounded by a congested ring, its margin is here and there ragged from granulations, which bleed on being touched with the

* Vide *Lancet*, April 14, 1849.

probe; this, on being passed along the uterine passage for an inch, was then arrested, although a very small one was employed. The cervix uteri was freely scarified, and bled freely; rest was enjoined, and a pill of blue pill, compound rhubarb mass and henbane, prescribed night and morning, with a draught of bitter infusion and nitro-muriatic acid, twice in the day. On the fifth day after, the speculum was again employed; the cervix has improved considerably from its congested and varicose condition, and the edges of the os were looking less irritable. The whole of the cervix within reach was pencilled over with the solid caustic, and the caustic and extract of conium, referred to in my last papers on this subject, passed up the "neck" by means of the bougie, which extended up at least an inch and a quarter. The dyspeptic symptoms were somewhat relieved; the pills were ordered to be repeated every night and the draught as before. This plan of local treatment was adopted every fifth or sixth day, until the next monthly period, when she had considerable pain, but only for six or seven hours, which departing, left the discharge free. On this subsiding, the speculum revealed an improved aspect in the cervix, which was much diminished in size, and the whole of the varicose and congested condition gone. The margin of the os was smooth, and the introduction of the probe followed by no bleeding; the passage was far more patent, and there was no difficulty in getting the instrument along to the extent of more than two inches. The internal applications of the caustic was to be continued as before, every five or six days, and she was ordered a mixture of the ammonio-citrate of iron, carbonate of ammonia, and infusion of calumba.

June 26th.—Mrs. C. was convalescent; her general appearance greatly improved; face stouter and of more healthy hue; her spirits better, and can take plenty of exercise without feeling other than usual fatigue. The dyspeptic symptoms have all but disappeared; her appetite is good; the tongue clean, but still somewhat pale; pulse 72. The monthly flow, which occurred on the 18th inst, commenced, and has continued (free and healthy in character,) without any pain or annoyance.

October 25th.—I have this day seen this patient, and the above favourable state of matters continues.

Remarks.—In viewing the history of this case, it will be seen that the uterine derangement was existing prior to the miscarriages referred to, and in all probability may be considered as the exciting cause of them; when, however, the mischief was clearly traced to the uterine passage, pregnancy did not occur, and several cases that I have met with clearly proved that the barrenness of the female did not occur from the dysmenorrhœa, properly so called, but was in consequence of organic disease of the communicating surface; this disease interfered with the peculiar suction power of the uterus, which not unfrequently seems to be considerably diminished, if not restrained altogether, by this affection. Looking upon this case as one of dysmenorrhœa, it must be referred to the third pathological cause. The mischief, it is worthy of remark, gave rise at first to the more common symptoms of ulceration of the cervix, and it is clear that it was a considerable time before the uterine passage became affected, when it gave rise to the painful periodical symptoms. As I have before stated,* when ulceration attacks the cervix, I have usually found that the ulceration centres towards the os and into the passage, and in its cure heals from the circumference to the centre, which is always well to be remembered, as a case may apparently be cured whilst there is still disease within the passage.

The next case is one which occurred in the practice of Mr. Paulson, of Mansfield, who kindly communicated it to me, and I take this opportunity of thanking him, as well as numerous gentlemen in the provinces, for letters received, detailing successful cases treated by means of caustic and the bougie.

Case 2.—"S. H., aged 23, resides in Mansfield, of rather a delicate irritable constitution, and small in person. Began to menstruate at 16, which continued very irregularly until about 20 years of age. The menses then appeared at intervals of about two months, accompanied by much pain, and very scanty. At this period a most distressing symptom occurred, viz., continued vomiting, so much so that she hardly ever retained a meal on her stomach. She married when 21, and the vomiting, with difficult and irregular menstruation, continued for two years longer. It is important to remark, that she had never become pregnant, and at the menstrual periods she suffered most severe pains in the back and abdomen, with much distension of the latter. She was, during the three years above described, attended by a medical man, who, conceiving the stomach to be the cause of all the mischief, after cuppings, &c., over that region, failed to afford her the slightest relief. On February 18th, 1849, I was called to her; I found the face, lips, hands, &c., presenting evidently the anæmic condition. She was reduced to a mere shadow and state of great nervous debility, by the incessant vomiting, with constant leucorrhœa, in fact she was so weakened that it was quite evident to me, without relief she would rapidly sink. The history of the case instantly led me to suspect the cause of her illness, and having ordered the appropriate medicines, (with only temporary relief,) I took the first opportunity of making an examination *per vaginam*. A few days after I introduced a dilating speculum into the vagina. The cervix uteri presented a vascular appearance, and was so much thickened and puckered, that the os could only be discovered by its depression. There was no ulceration, but a distinct false membrane, very vascular, stretched over the *os uteri*. I passed the end of a catheter through this membrane, and into the *os uteri*, with some difficulty, and attended with slight hæmorrhage. This operation I continued to perform at intervals of a few days, until the parts seemed to me to possess a permanent passage, and were sufficiently dilated. In about six weeks the menses appeared in proper quantity, and without pain. There was no

* Vide *Provincial Medical and Surgical Journal.*

distension of the abdomen, the vomiting seemed to be arrested magically, and my patient improved in every point of view. Her appetite returned, she retained her food, and was soon able to leave her bed entirely. A more important fact is still to be added. Within a month or so of the catheter having been introduced, she must have, for the first time, conceived, for it is only a few weeks ago that she miscarried,* the fœtus being at least, of three months' formation. She now enjoys good health, the tone of the stomach thoroughly restored, catamenia regular, and without the distressing symptoms hitherto attending them."

The above case is highly valuable and instructive, as exhibiting how severely the frame may be affected by apparently a slight local affection, and how effectual the application of local means was in curing disorder, which had for so long a time withstood the employment of probably well-directed general ones. The case is also very important in showing how obstruction produced dysmenorrhœa, and how readily it yielded when this obstruction was overcome. The above case might probably be thought to be simply one of a naturally contracted os and cervix; but, on carefully looking over it, I am disposed to view it as belonging to the same cause as the last recorded, but without any ulceration of the cervix; for Mr. Paulson remarks:—"The cervix uteri presented a vascular appearance, and was so much thickened and puckered that the *os* could only be discovered by its depression." There was no ulceration visible, yet a little farther on he remarks that "the passage of the catheter occasioned slight hæmorrhage." This I have uniformly found does not take place without the mucous membrane is in a diseased condition, presuming, of course, that proper care is employed in the use of the probe. This disease in the mucous membrane of the uterine passage in all probability came on, I presume, at the age of 20, when it is reported that the menses were scanty, and accompanied with much pain. The vomiting also appeared at the same period. The introduction of the probe acted as a stimulant, changing the perverted action of the mucous membrane, and promoted interstitial absorption, thereby diminishing the size of the cervix and increasing the patency of the passage.

Case 3.—The *third* case is that of a young unmarried lady, aged 21, who has been troubled for nearly three years with disorder of her general health, attended with great debility, emaciation, and indigestion; for the same period she has also suffered greatly from dysmenorrhœa, and has frequently to lay by for a day or two at her periods. She first came under my notice on August 13th, 1849, and was then complaining of an increase of all her symptoms. Her face was pale, and the lips and gums colourless; the hands and feet cold; her weakness extreme, so that to walk a hundred yards was almost the extent of her capability; pulse 124; tongue much chapped and very sore, red round the edges and slightly furred at the back; appetite little, and the food digested with pain and much flatulence. She complains of slight difficulty of breathing, and has been troubled with a "tickling cough" for some time, so much so as to cause alarm amongst her friends of consumption. The stethoscope reveals, however, no mischief. A nervous bruit exists in several of the larger vessels. All the secretions appear to be performed with regularity. The catamenia, however, are scanty, accompanied with small shreds and occasional clots, and attended with great pain, both previous to and during the first day or two of the flow. The vagina is relaxed, and there is abundant leucorrhœal discharge, which has existed more or less for the past three years. The speculum discloses a cervix somewhat enlarged and indurated, and an irregular-shaped ulceration of about the size of a small almond, which embraces a part of the os, and extends up the uterine passage, bleeding upon the slightest touch. The nitrate of silver was freely applied externally to the cervix, and a probe, smeared with the extract of conium and caustic, introduced about three quarters of an inch up the uterine passage, which was as far as it would permit. One of the following pills was prescribed to be taken three times a day, viz.:—R. Quinæ Disulph., Ferri Sulphatis utrq., gr. xij; Strychniæ, gr. ss.; Conf. Rosæ, qs. ut ft. massa in pilulas xij, distribuenda.

An injection of alum and tannin to be used twice a day. After the medicines had been taken three weeks, and the local applications employed three times, the catamenia appeared more abundantly, healthier in appearance, and with only about four hours pain in lieu of forty-eight and often more, and which at no moment was so violent.

October 28th.—Up to this time the treatment has been steadily pursued, and I find that the ulceration has entirely healed, and the leucorrhœa all but gone. The probe can be made to pass an inch and a half easily, and unattended with bleeding. The last *period* passed over without much pain, in fact without any, with the exception of a bearing down, which prevented her from standing many minutes together. Her general health is considerably improved, she has walked on several occasions during the past week a mile or two, without fatigue. The indigestion is considerably relieved, her appetite being better, and the tongue has almost lost its chapped and sore condition. Her spirits have much improved, and her cough is gone. The strychnine in smaller doses was continued, and a mixture of the citrate of iron and quinine prescribed. Is to take an occasional aperient of blue pill, henbane, and colocynth. The bougie is to be continued at intervals for seven or eight days.

November 25th.—Her general health is still further improved; the digestive apparatus has regained its usual tone; tongue well; pulse 76, stronger. Her muscular strength is much greater and can take plenty of walking exercise. She is also stouter, and is regaining a little colour in her lips and cheeks. She has lost all pains in the back and hypogastric region, her spirits are higher, and she begins to enjoy society, which for the past nine or ten months has been irksome to her. Upon introducing the speculum the cervix uteri and

* The letter accompanying this case was dated August 28th, 1849.

surrounding mucous membrane was seen discoloured from the commencement of the catamenial discharge, although she was totally unconscious of the fact. The collateral history of her family inducing me to believe that scrofula had tainted her system, I strongly recommended the use of cod-liver oil to my patient for some time, my experience having made me think highly of its value in this scourge.

December 30th.—Another period has passed over without pain. She is better in every respect, and in point of fact is convalescent.

It is singular to notice in the above case how much disease existed in a young unmarried female, wholly beyond those influences supposed generally to determine much of the disease of this character, viz., ulceration of the cervix uteri. The local disease was clearly not so prominent as any one of the *general* symptoms, for neither of the medical practitioners in attendance previously, had had their attention directed towards the womb, as the primary excitor of the disordered health. Still she distinctly stated the fact that some of the leading symptoms of ulceration had existed prior to the period of her general health giving way, but her sense of delicacy foolishly prevented her mentioning them, to wit, a *bearing* down, leucorrhœa sometimes *coloured*, pains in the back, groins, and hypogastric region. The dysmenorrhœa, it will be noticed, gradually ceased on the diseased condition of the mucous lining of the uterine cavity diminishing, and in fine, totally disappeared before I could satisfy my mind that the diseased state was quite cured. The above was one of those cases which are commonly called "dysmenorrhœa with membranous formations." There was nothing peculiar in it beyond any that I have seen where there was no membrane at all thrown off, other than that I observed there might have been an increase of those symptoms usually indicative of uterine conjestion, just previous to the monthly period. The nature of these membranous formations has given rise to much discussion, and many and divers opinions as to their true character; additional examination and more extensive experience lead me still to believe that which I have elsewhere expressed, that they are nothing more than a product of the diseased mucous membrane, taking on that peculiar form of action which other mucous membranes are known to do; *e. g.*, those of the urethra, trachea, and intestines, in fine, nothing more nor less than an effusion of organizable lymph. There was one circumstance I noticed in this case, which slipped my memory when mentioning the history of it, viz., that I observed from the first of my attendance a very large size of the clitoris which was also considerably indurated, so much so as to protrude beyond the vulva. As, however, the diseased condition of the uterus subsided, it also became reduced in size, so that latterly it was very little, if at all, larger than ordinary. I have heard of such a state of matters existing in connection with nymphomania. Not a vestige, however, of sexual excitement was apparent in the above case, but it would be worth while remembering, were such a painful disease to present itself, to inquire whether any irritating organic disease was existing in the uterus itself to account for it.

Case 4.—Miss H., aged 21, of weak and sickly aspect, applied to me for relief. She is a governess, and, being an orphan, is dependent on her own exertions for support. She states that she first began to menstruate at sixteen years of age; it came on very irregularly at first, and scanty, but always attended with extreme pain; in the intervals she has never had any symptoms which lead to the supposition that uterine mischief ever existed. Up to the present period, April 20th, 1850, the dysmenorrhœa has rather increased than dimished; and although she has had the advice of several medical practitioners, palliative treatment has been all that has been recommended—morphia and antimony, warm baths, &c., &c., at the periods; iron, bark, &c., &c., in the intervals, to give vigour and tone to the system. All, however, has been to no purpose, for at this time, April 20th, she is just recovering from one of the attacks, and is weak and feeling ill, wholly incapable of any mental or corporeal exertion. The pains generally come on at least twenty-four hours previous to the appearance of the discharge; she is compelled to keep in bed, has cold shivers, her face and hands change to a blueish hue, and her whole system is prostrated by the violence of the uterine efforts. Usually on the third day the pains subside, and she is left languid and weak for many days subsequently. This state of things seriously interfere with her duties as a governess; and she was induced to apply to me from a knowledge of a similar case having been cured under my care. There was no symptom in her case which led me to infer uterine disease, and I looked upon it, in all probability, as one of a naturally-contracted os and uterine passage, especially as she had been affected with the dysmenorrhœa from the first of her menstrual life. The speculum disclosed this to be a correct view. The vagina and cervix were healthy, but the os it was difficult to find, the only appearance of it being the merest depression; no probe that I could get would enter it in the slightest degree, with all the pressure I dare exert. Under these circumstances a slight incision was made at the point mentioned, by means of a spear-shaped lancet, and I was then able to pass up a very small metallic bougie about half an inch.

On April 26th I again passed up the same bougie, and, after some little trouble, was able to introduce it up somewhat higher, viz.,—to the extent of nearly an inch. This operation was repeated every fourth or fifth day, with an increasing sized bougie, until the 15th of May, when menstruation again came on. It was attended this time with decidedly less pain, still it was considerable, but not so persistent. On May 22nd I passed up a small sponge tent, but it produced so much pain that I was compelled to withdraw it. The bougies were consequently continued every three or four days, and kept in for ten minutes, at a time, sometimes longer. On May 28th I find recorded that the whole of the uterine passage was larger, and that

I could pass a small instrument at least two inches. On June the 10th the catamenia again commenced; the pains were considerably lessened, and only lasted five or six hours. Her health has much improved. Up to August the 30th the bougie has been occasionally employed; two periods have passed over with but trifling inconvenience, and she considers herself well.

The above case is clearly an illustration of the first cause; and the obstruction which existed both in the os and uterine passage, together with the result of treatment specially devoted to the overcoming of that defect, incontestably prove that in this case, at any rate, obstruction was the sole cause of the dysmenorrhœa. There was no disease in the passage, or any disorder of the general health, which could account for it; but on the obstruction being lessened the pains were immediately dimished in severity. This was the first case which ever came under my notice that required the use of any cutting instrument; but it was rendered necessary by the condition of the os uteri, which would not allow any probe which I had to enter it. After the enlargement of the uterine aperture, I was enabled to pass a small bougie half an inch, thereby showing that that was the narrowest part. Professor Simpson, of Edinburgh, informs me that he has long put on one side bougies and tents for the more potent means of incising the cervix uteri. I must confess that, theoretically, I am disposed to view the incision of the uterine passage as an operation of no very trifling importance, for two cases have been reported to me in which the operation had been performed; in one the hæmorrhage was extreme, and very alarming, in the other the incisions got well, and left the passage as impervious as before. To render incision successful, it does appear to me, therefore, that the bougie should be also had recourse to subsequently to the operation for some time, and therefore on the score of the repetition of a delicate manipulation, the one is no better than the other; besides, it would be wise to anticipate a little, and reflect how would this mutilated cervix and os dilate on the approach of labour, should the subject of the operation become pregnant? I have now treated very many cases of dysmenorrhœa successfully by means simply of the bougie, aided by the employment of caustic, and the success I have met with induces me to persevere in a plan that is not open to the objections which incision exhibits. This latter could only be applicable to cases arising from the first and second causes, for where disease exists in the uterine passage, it could only act as a temporary remedy. We must overcome, likewise, this disordered condition of the part at the same time that a permanent passage is maintained, and this, my experience teaches me, is best obtained by the tent or bougie—the latter of which I almost exclusively make use of—the judicious application of caustic, and properly directed *general* treatment.

Case 4.—The following illustration occurred in the practice of Dr. Wardell, late of Acacia Road, Regent's Park, by whom I was requested to see the case, and for the particulars of which I am indebted to him:—

"Mrs. B. applied to me October, 1848, for what she supposed was mainly an affection of the stomach, giving rise to a considerable degree of general debility. Hair auburn; eyes blue; volume of flesh below healthy standard; the countenance looked pale, and somewhat haggard; pulse soft, and easily compressed; skin relaxed, and abdomen tumid. States that she has much flatulency, and her appetite is greatly impaired. During the previous twelve months has complained of the following symptoms:—Catamenia frequent, and sometimes profuse; at times would be unwell twice in the month. She has lost *blood* occasionally per vaginam, and also at stool. Has had a leucorrhœal discharge, which is often tinged with blood; during this time dysmenorrhœa made its appearance, and the pains have gradually increased in severity, especially during the last five or six periods; they prevent her from following her avocation for at least twenty-four to thirty-six hours. She never complained of dysmenorrhœa previous to the last ten months. Ascarides have recently been noticed in the stools. She is highly nervous and excitable, and has much palpitation on any increased exertion. Examination per vaginam showed the parts to be relaxed, and unnaturally lubricated; the uterus was lower down than natural, and a small tumour, of a pedunculated character, could be distinctly felt emerging from the os uteri. On introducing the speculum the tumour was readily seen, of a red colour, and of a fibrous and vascular appearance; it bled upon being but slightly touched, and presented an irregular fissured surface, some oozing of white creamy-looking matter took place from the os on the tumour being held on one side. The tumour was of the size of a large flattened cherry. It was removed by long torsion forceps, when two to three ounces of blood escaped. The hæmorrhage being arrested, caustic was freely applied, and this application repeated on the next two or three visits. Vermifuges were given, which speedily removed the ascarides, and the tincture of iron, in infusion of calumba, regularly taken, with an occasional dose of blue pill and colocynth at bed-time. In a few weeks she felt much stronger, the pulse was firmer, the appetite greatly improved, and the dyspeptic symptoms had disappeared. The hæmorrhage per vaginam ceased, as also the leucorrhœa, under the use of an injection of a weak solution of nitrate of silver. The dysmenorrhœa disappeared on the removal of the tumour." Dr. Wardell, in a letter dated April 4th, 1851, states:—"This patient remained quite well when I last heard of her."

Remarks.—The above is an example of the fourth pathological cause mentioned, viz., obstruction of the uterine passage from tumours or other morbid growths. It will be seen on reading over this case, that the dysmenorrhœa first began to torment her some two or three months after the uterine symptoms were observed, and continued, under the treatment of various medica l men, to trouble her until after the growth was removed, when it entirely ceased; there can, therefore be scarcely any doubt as to the fact, that the obstruction was the cause of the pains, although some may attribute it, in P art, to the irritation of the lining membrane of the

womb from the presence of the tumour. Some months ago a case of dysmenorrhœa came before me, arising clearly from obstruction, induced, however, by a wholly different cause, viz., anteflexion of the uterus, and brought about some short time after an attack of metritis. On the deviation in form being remedied, the dysmenorrhœa ceased. I trust to have, before long, the particulars of this case, which I shall lay before the readers of the *Provincial Medical and Surgical Journal.*

Case 5.—Mrs. F., aged 33, married, applied Oct. 4, 1850, for advice under the following circumstances:—She states that three years ago she was ill and under the care of two medical gentlemen, who both treated her for ulceration of the uterus. She was under the first nine months, and the second nearly two years; during this period she was frequently subjected to the application of caustics, and on several occasions the potash caustic was applied. The ulceration at length disappeared, and with it the symptoms which she had complained of, and which were symptomatic of the affection; in lieu of these, however, dysmennorrhœa, which had troubled her through her illness more or less, increased considerably, so much so as to induce her to apply to me solely to relieve her of this periodical annoyance.

Mrs. F., I find, has been married thirteen years, and never been pregnant. Her general health is tolerably well, but she complains of a constant burning sensation about the womb, which, coupled with the dysmenorrhœal pains keeps her weak, and her mind distressed with a fear of worse evil. There is no leucorrhœa, and she is quite "regular." There is great complaint, however, of nervous dysphagia. On examination with the finger I find the neck of the uterus larger than ordinary, but without pain, and the whole organ heavier and more indurated than natural. The speculum reveals no ulceration, but the os looks simply like an indentation, with the surface around it, to the extent of the size of a fourpenny-piece, puckered as if from a cicatrix. I attempted to pass a small probe about the size of the ordinary one in daily surgical use, but without effect, for on pressing it over the indentation, it slipped away as if no opening at all existed. I then tried to insert the fine wire which forms the stilette of a catheter, but this also would not pass. Under these circumstances, I introduced for about a quarter of an inch the perforator of a hydrocele trocar; the probe was then made to pass with a little difficulty for about three fourths of an inch, when its progress was not delayed, the obstruction evidently existing in the first portion of the uterine passage.

5th.—I passed a large bougie, coated with the caustic; it was more readily inserted than the day before, but still required a considerable amount of pressure. There was no bleeding from the puncture. Every two or three days subsequently to this, the bougie was passed, either the same or a larger sized one, until an instrument the size of a large goose quill would enter with facility. Every fifth or sixth day the whole of the cervix was also pencilled over with caustic.

November 2nd.—I find recorded that she had just recovered from her monthly period, that it had come on without pain and continued throughout so, excepting on the first day for about two hours. On examination, the large bougie passed very readily, the cervix to the touch appeared softer, and I was consequently induced to go on with the application of the caustic and pass the bougie at intervals for another month. She was to take the following twice a day. R. Syr. Ferri Iodidi, dr. j., Tinct. Sumbul, m. x.: Aquæ Cinnam., oz. iss. M. Fiat haust.

Dec. 15th.—The dysmenorrhœa did not return, the uterine passage continues well open, the cervix gives a more healthy sensation to the touch and the general health has decidedly improved. She went into the country two or three days subsequent to this date. The dysphagia has also ceased.

March 10th, 1851.—A relative informed me this day that Mrs. F. continued free from her malady.

Remarks.—The above case is an illustration of the second cause spoken of, viz., a contracted or strictured condition of the passage through the neck of the uterus, from previous inflammation or ulceration. Previous to the diseased condition of the womb, there was no dysmenorrhœa, but during the course of treatment it came on, and increased considerably after the ulceration was cured. The appearance of the os and its surrouning surface, induces one to ask,—How far the effect of the deep cauterizations with the Potassæ Hydras may have been the cause of the contracted condition of the passage? My own impression is, that it was; and reasoning from its effects in other parts of the body, I think we are justified in the conclusion. I have applied the solid nitrate of silver around the cervix, and oftentimes up the uterine passage, without occasioning such a result in the slightest degree; and I take this opportunity of again repeating, (with considerably increased experience,) that which I urged in a paper read before the Provincial Medical and Surgical Association, at Bristol in 1847, and printed in the *Journal* Sept. 8th of that year, viz., "in the generality of cases that have occurred to me, the nitrate of silver has answered all the purposes of an efficient caustic, and that I cannot but view the actual cautery, the Vienna paste, the pernitrate and acid nitrate of mercury, as well as nitric acid applications, of too violent a character for ordinary use to that portion of the body." Since that time I have never met with a single case of ulceration, engorgement, or induration of the uterus, that I have not overcome by means of the lancet, *lunar caustic*, and last, but decidedly not least, by *general* treatment. I am convinced that by some practitioners on uterine diseases in the present day, too narrow a view is taken of them; the diseased womb is looked upon as if it were isolated from the rest of the body,—as if it had no connections—no sympathies. The fact is too often lost sight of, that its morbid states may be, and I believe often are, the result of a morbid condition of the general system. The adoption of specialities at the present time, however valuable in some respects, has an

injurious tendency in others. A physician who has directed his attention exclusively to diseases of a particular part, or who has chained himself down to one particular mode of investigation, is often apt, as I remarked before, to take too narrow a view of disease; and when general symptoms exist in the patient who applies to him, which he cannot well account for, from his limited practical knowledge, he is led unconsciously to distort them to his purpose, and fixes upon his "hobby-horse" (whatever it may be) as the seat of his patient's malady. The local disease is consequently attacked, whilst the depraved state of the system, which frequently gives rise to it, is neglected. Simple ulceration of the womb is, I am more and more satisfied, oftentimes an effect of a disordered condition of the general system, and should be met equally by general remedies, as by the application of local ones; the judicious adoption of the former will occasionally obviate the necessity of the latter, and when this is indispensable, the *general* treatment will generally shorten the period of the requirement of the *local*.

7, Upper George Street, Bryanston Square, London,
March 29, 1851.

SEXAGENARIAN THOUGHTS
ON THE
PRESENT STATE OF THE MEDICAL PROFESSION.

To the Editor of the Provincial Medical and Surgical Journal.

Mr. Editor,—The present divided, and I might add degraded, state of the medical profession, must be admitted on all hands: nor does it appear that a remedy for this state has as yet been devised. I do not pretend to suggest such remedy; and yet, perhaps, the observations of a sexagenarian, who has never taken a part in professional politics, and who is therefore unpledged to party, may not be undeserving insertion in your columns.

Of course the younger practitioners expect much from *legislation*, and think that their standing will depend upon the manner in which they are recognized by the laws. Fully approving of the protective influence which may be thrown by law around the practitioner's general character and acquirements, I cannot admit that this legal standing will constitute any real test of his value; for it must be known to every one, that a young man studies for his *diploma*, and not to acquaint himself with disease and its remedies; and that having once passed his examinations for the Hall and College, he thinks himself fully qualified to enter upon his responsible duties as a practitioner, and therefore studies no more.

Forgive me, Mr. Editor, for speaking of myself, for I am one of those persons who possess no diploma. During my hospital career—now more than forty years since—I was known as a hard student, and was remarked by all my compeers, as one whose untiring diligence was proverbial and worthy of imitation. I availed myself of all the advantages then offered me, to become acquainted with my profession; but at the close of my hospital studies, I found that the *res angusta domi* precluded my taking a diploma, which would involve a considerable expense, and which in my opinion would not add to my real worth; and I was far too proud to obtain certificates which I saw daily given to the idle and the empty headed. I have had reason many times in the course of life to regret this decision, but it was taken from the pressure of poverty, and I confess that I do not feel it quite just or kind, that I should now be said to be found among the "refuge for the destitute—those who were in practice prior to the year 1815;" and that simply, because the money which might have been saved for a diploma, was expended on the acquisition of a more thorough knowledge of my profession. Settling in a provincial town, I had a hard struggle with the difficulties of a young man, without fortune and marrying early; but I struggled on, for I felt that the weight of my own character was such as must ultimately give me influence. I early commenced a literary career, and my pen aided me in the wearisome journey of life; my hospital has been always proud to acknowledge me as one of its alumni; my professional friends, many of whom were among the first men of their day, have always taken pleasure in listening to me, and advancing my interests, and I have felt proud in acknowledging their esteem. I have acquired a reputation, which may be termed *European* rather than *British*; and I have oftentimes looked down with pity, if not with a feeling allied to scorn, on the miserable starvling intellects, who were enjoying their diplomas, but who were glad to consult me in their emergencies. The result has been that I obtained a large practice—and a large *consulting* practice too;—that I was sent for from long distances through neighbouring towns;—and that during my maturest and most active years of life, I enjoyed a practice scarcely ever equalled in the country for its extent or its returns. Known extensively throughout the kingdom, my position among my professional brethren has been that of an intelligent, literary, well informed, observant practitioner, whose opinions were always worth having, and to which many would yield, because they were always formed on rational grounds, and could always be defended by argument. In the course of life, therefore, I have had much to be thankful for, and have experienced much success, to which, however, I feel that I was justly entitled by my superiority. But I have experienced many a mortification from a *dwarf* obtruding his diploma upon my notice, and giving me to understand, that he had an authority to practise which I did not possess; and when upon an occasion of a trial for child murder, it was remarked by the late Lord Tenterden, that he had *never known* such medical evidence given in a court of justice in his life—that it did not leave a loop-hole for the criminal—and that he considered it as highly complimentary, it was whispered in my ear, as a wonder,

that I had ventured to give evidence at all, without the sanction of a diploma; and this too, by a jackanapes who had not given as many minutes as I had weeks to the study of medical jurisprudence. The most deeply mortifying occasion to me, however, was only a few years since, when I was offered the *Fellowship* of the College, and could not take it because I was not a *Member*. So while I have insisted upon professional character being something *detached* from a diploma, I also insist upon it as being still more valuable to its possessor, when *attached* to, or *coupled with* a diploma.

And now you will see, Mr. Editor, from this portion of autobiography, how completely my prejudices are set loose from any of the existing corporations, and therefore how free from sectarian bias must be my observations, as they have been chronicled in my own thoughts. For many years past I have heard and read much about medical reform, though I have never handled the *vexata quæstio;* but how comes it, that after years of pursuit of this phantom, and after a great improvement in the professional standing of the great mass of practitioners, their grade is less esteemed by the public than it was formerly, and that their gains are trenched upon on every side. I lately made a complaint to one of the most distinguished novel writers of the day, that he had never drawn a medical man in his best colours. True, said he, but I have drawn my characters from the life—as I found them, not as you would wish them to be; the very best of them were *humbugs*, and there is scarcely one who could give *a reason* for the practice which he adopts.

Within the last forty years circumstances have materially changed, and *one* very important change is, that with the exception of the manufacturers, everybody has become comparatively poor; from various causes their income has been lessened, and they have looked around them for the means of retrenchment. The attendance of a medical man upon all ordinary occasions has been voted an expensive luxury, and with the aid of encyclopædias and treatises on domestic medicine, patients have thought themselves qualified to prescribe for themselves and their families, and they have done so, to the great detriment of professional income. True, that they would occasionally get into a little hobble, through the severity of the case, or their misunderstanding its nature, or their faulty prescription for the same, and that they would then send in a fright for their medical attendant, who perhaps *then* would come in too late to be of service, and would have to bear all the blame of a failure, which actually belonged to the parents. But, inasmuch as in the greater number of instances the tendency of malady is to get well, and of the energies of the constitution to restore its equilibrium by the *vis medicatrix naturæ*, so in the greater number of instances, recovery would follow parental medication, and the parents would be emboldened to go on, while they would also calculate how much they had added to the resources of a straitened income from this plan of self-prescription. Now, this is the foundation of that system of quackery which pervades society, and which must detain us for a few minutes.

There is afloat in society a sufficient amount of common sense to perceive, that while medical men are vehement in their denunciation of quackery, they are themselves the greatest quacks, for they prescribe, not for the individual patient, and for the various organs and functions disturbed by constitutional irritation, but *for a disease*. Give it a name, and it must be treated after such a plan made and provided in such cases;—or they take a prominent symptom, and prescribe for that symptom, varying the treatment as often as this same prominent symptom varies;—or they have for the time being one favourite remedy, which, as lord of the ascendant, is prescribed for every disorder, and is endowed with an influence which may be almost termed *universal;*—or they will stand quietly by, and watch the progress of disease, waiting for indications, till the golden time for interference has passed, never to be recalled, and the patient is inevitably lost;—or they become so exclusive in their views as to see but one form of malady for ever presenting itself to their notice;—or they will fall in with the whims and caprices of their patients, and have no fixed opinion of their own, always siding with the views of the patient or his friends, which, it need not be said, are generally as absurd as ignorance, guided by folly and prejudice, can make them; and thus the patient is conducted to this inference—that there is nothing *rational* in the treatment adopted for him; hence he jumps to the conclusion that there is nothing *rational in medicine*, and finally he falls an easy prey to any system which promises largely, which vaunts its cures, especially which can be readily managed by *himself*. Self-love, that all-absorbing sentiment and passion, is also a principle which lies at the root of the special quackeries of the day, and it is in the diffusion of this system of quackery that much of the diminution of professional income of the present day is to be found. That such income has suffered every medical man will admit; that it should have been lessened, in consequence of the diminished expense of conducting practice, and of keeping a family, is acknowledged, but it has suffered far more than the equivalent of this; and of all the medical practitioners in the kingdom, there are very few who are keeping themselves and their families upon their *professional income*.

The great forms of quackery which address themselves to the understanding, or the *would-be understanding* of patients, are *hydropathy* and *homœopathy*, Here the plans are apparently so *simple*, the means so easy of application, and the medicines so little onerous, while the absorbing principle of self-love is gratified by becoming one's own doctor, that it is easy to understand how the patient is led by strong motives to cast in his allegiance to principles which he fancies he can understand and which *promise* so largely. In this latter consists the principle which absorbs and ensures the confidence of the patient. The regularly-educated and well-informed practitioner will never promise largely, because he knows how little he is in possession of all the circumstances which modify and change the influence of his remedies, and how little he is acquainted with all the complications of disorder, which baffle

oftentimes the best digested plans, and leave him a *disappointed* but not a *disheartened* man;—*disappointed* from want of success, but not *disheartened*, because he knows he has done the best he could.

We suppose, however, the patient to be ignorant that the first principle of homœopathy was based on fallacy and built up in error—an error proceeding from the fact of ascribing all the feelings of the body for three months to have been produced by an infinitesimal dose of some harmless remedy. Let us suppose him to be absorbed and infatuated by these *simple and well understood remedies*; is it the fact that they are *so simple*—so well understood?

Water is apparently a simple remedy, and if used for the simple purpose of universal ablution, it is unquestionably an admirable remedy in preserving the skin—in removing from its surface all its excretions, keeping it in a healthy condition, promoting its own most important offices, and thus tending to the preservation of the healthy function of the mucous surface of the stomach, with which it is in close sympathy and alliance,—suffering in all its sufferings, and equally healthy when it is healthy. This most important and, I fear, too neglected process should be constantly upheld and earnestly recommended by all. But when we go further—when we come to the application of the wet sheets, and the sitz bath, and large ingurgitations of water, is it so certain that we know the end from the beginning;—that we are resting on secure grouud, and that we are so thoroughly acquainted with the operation of our agents as is assumed? As an universal panacea, can it be applicable to every kind, and form, and stage of disorder? Is it a matter of so little importance that in all cases the blood should be deluged with water, or that the excreting organs should be so taxed to eliminate the excessive quantity swallowed? Is it a matter of so little consequence that the wet sheets should be daily applied, for so long a time, to the entire surface of the body? Do we thoroughly know its influence, direct and indirect, immediate and remote, consequential and contingent? My experience of hydropathy has been unfortunate. I have known in my own circle eight patients who have thoroughly employed it under the best and most approved methods and most celebrated masters. One only of these speaks largely in favour of the remedy, as having cured him when regular medicine had utterly failed. Of the remaining seven four died from the progress of their several diseases; the other three became insane, two died by their own hands, the remaining third has eventually recovered under judicious treatment. Now, I am not about to say that these were consequences, they might have been coincidences; but, at any rate, a remedy which might be the occasional cause of developing these tendencies, and of hastening the progress of destructive malady, is not one to be lightly employed,—is not one to be employed at the bidding of the patient himself,—is not one to be employed universally, nor under the sole guidance of one of the apostles of hydropathy.

It has happened with hydropathy, as well as with homœopathy, but especially with the latter, that it has obtained a sanction from the good opinion of some wise men, who, from witnessing the injurious effects of medicine injudiciously employed, and having studied the thoughtless quackery with which it is prescribed, have arrived at the conclusion that medication did more real harm than good in this world, and that the less there was of it *the better*. Now this has been an unhappy and unsound conclusion, because no true philosopher ever argues against the use of a remedy from its abuse; and, besides, it has afforded a pretext and given encouragement to others, who, without such an exuberance of brain, have been glad to find a shelter for their own ignorance or indolence in the unthinking dogmas of "Young Physic,"—in that do-nothing-system which justifies the practitioner in waiting for and watching the curative agencies of nature, and seeing whether she will not effect a cure unaided by medicine. This is an unhappy result from the crotchetty doctrines of great minds, for their *own* doctrines in their *own* hands, will only lead them to be cautious not to *over-physic* the patient, and to watch, and study, and develop indications, which they will gladly seize, and improve, and act upon. But their disciples will take up this waiting as a most convenient resource,—as an excuse to save them from the trouble of thought: and so the patient will be suffered to die rather than that the medical attendant should be at the trouble of making out the morbid actions, which are to be repressed;—or the languid actions, which are to be assisted;—or the depraved and perverted actions, which are to be remedied;—or the arrested actions which are to be restored. And this has been fostered by another very fashionable plan of the present day, viz., by making a charge for visits and none for medicines, or by giving the patient a prescription to get dispensed at the druggists, and to let the prescription be as inexpensive as possible; and this arises from the thought of its being a *degradation to dispense one's own medicine*. It is very easy to be above our own position; it may be agreeable to be saved the trouble and expense of keeping a dispensing assistant: but the question is, not what may best foster our own pride, but what is really for the good of the patient? Can you in any other way secure your patients obtaining a supply of medicine upon whose agency you can confidently rely? If this question be answered in the negative—and it must be so answered—the point is settled at once; and it becomes the positive indefeasible duty of the usual medical attendant to provide medicine for his patient, and also either to dispense himself or to provide a dispenser. Now, I freely admit that it is disgraceful to our profession when you see a man, with the diploma of the Hall and College, keeping an *open shop*, selling drugs, patent medicines, perfumery, horse and cattle medicines, tooth-brushes, &c. &c. These things are within my own knowledge, and they are disgraceful; but I can see no disgrace attaching to men prescribing for their own patients, providing them with medicines, and dispensing these medicines. On the contrary, I honor such men, because they prefer the good of their patients to any other selfish consideration,

to any consideration prompted by their own pride, and yet who are too proud to join in the cry of those who wish to get quit of the burden of prescribing medicine, to be dispensed by their own dispenser, whom they will have to keep at a cost of £80 or £90 a year; or to perform this office themselves. All honor to such men—to those who cannot afford to pay for this service rendered, and therefore perform it themselves, and not by deputy. Indolence and greed are the two grand motive principles at the head of that section of our profession which abjures this unselfish process. Now, I fully approve of the plan of remuneration not being in the shape of medicine; let every visit be paid for as such, and let the supply of medicines be included; then there will be no temptation to give *too much medicine* on the one hand, and no temptation on the other to withhold that which ought to be given.

But it is no easy matter to effect this change. There are among our patients, and among the higher classes too, those who do not like to pay an equivalent for medicine, if it has not been sent in the old form. An instance of this kind has recently come before me. A patient, residing four miles in the country, had been formerly visited at 5s. a journey, and four draughts during the day if the case were an acute one, or during two days if the case were a chronic one, and the journies were only on alternate days, and paid very cheerfully, has been lately acutely ill, has been prescribed for by a London physician, who ordered a mixture, containing four draughts, and the charge for journey and medicine 10s., although less than before, was resisted, because *a mixture* only had been sent, and a mixture had formerly been charged only 2s. 6d. Similar feelings and conduct in country practice continually occur, and the adoption of one universal plan is therefore not readily to be effected; in many instances it is perfectly easy, but in others impracticable, and at present the public is not ripe for a change, which by putting all into one comprehensive sum, gives an opportunity to the practitioner of charging much more than he would have done under the old regime. It is not easy to meet all the difficulties of the case; if a charge be made for medicine, you incur the odium of sending too much, in order to increase your bill; if a charge be made for visits, you equally incur the odium of making more visits than necessary or agreeable; if one lumping sum be made for medicine and attendance, you incur the odium of charging extravagantly; if a charge be made for visit and prescription only, you are blamed for making the illness more expensive *quoad* the medicine prescribed and the druggist's bill; and I believe the most agreeable plan for the practitioner is to engage with his patients for a certain annual stipend. Then he is the only sufferer, because he is sent for for every trifle, and is never thought of doing too much, he is only accused of doing too little; and if he be a zealous practitioner, he finds himself liberated from the fear of doing *too much* for the sake of gain, and can therefore conscientiously send the medicine he thinks necessary, and for as long a time as he pleases, and he most willingly and perfectly does his duty by his patient, careless of results, only knowing that the injustice, *if there be any*, is on his own side of suffering, and cheerfully throws this also into the scale. Still I would always have the general practitioner furnish and dispense *his own* medicines; he will then find the results he expects from his medicines, and will rest securely upon his pillow, from the conviction that everything has been done for his patient that could be done.

There is a fearful error very rife in our profession, viz., that of imagining that a man's education finishes when he has passed his examinations and leaves the hospital, whereas it is only just beginning; he has, indeed, laid the foundation of preliminary knowledge, but to educate or draw out that knowledge, can only be by the study of disease at the bed-side, by most diligent reading at home, and by comparing the symptoms during life with the organic appearances after death. All these sources of information are too much neglected: gentlemen do not study disease with sufficient attention; if they do not dispense their own medicines, they never can securely watch the agency of medicine upon disease. They neglect *post-mortem* examinations, from the inconvenience they occasion; and they limit their reading to one or more of the journals of the day, and perhaps to a particular abstract or retrospect. This will never do; holders of a diploma will not become sound or good practitioners upon so starvling a dietary for the mind; they must be fed with good substantial food, not previously half-digested;—they must study disease in its separate treatises, and compare them with bed-side phenomena, and then they will become learned practitioners—no matter what you call them; and to those who do not thus read and study, I would propose to append the privative particle *a* before all their titles of honour, and then, alas! how very few should we find without this stamp of imbecility.

It has been the fashion of the last few years to shout against the Apothecaries' Company as being a *trading community*;—as if there was no honour in possessing its certificate;—as if it was disgraceful to submit to the examination of such a *trading body*; and as if it was very desirable to separate from that corporation. Now I cannot quite make a distinction between the man who sells his opinion *simply*, and the man who does so, accompanied by the most effectual means of realizing that opinion; and it appears to me that each stands in precisely the same moral and intellectual light, though it may be more agreeable to the pride of the one, to say he has nothing to do with trade, and more consolatory to the conscience of the other, that he is honestly and truly seeking to effect all the good he can to his patient by administering his opinion and his medicines; and it is my decided conviction, that only those who keep shops,—who prescribe over the counter, and who sell *medicines as such*, not as a prescription, who are to be confounded with tradesmen; and in large towns, especially in London, there are many who do so, and yet hold themselves very high, invested with the panoply of a double qualification.

But with regard to the Apothecaries' Company, I say it advisedly, their certificate is a far greater honour

than the diploma of the College, when deprived of the artificial halo which surrounds the latter. Who is it that has given the impetus to professional acquisition? Certainly the Apothecaries' Company, by requiring a given amount of education, and by testing its possession in their candidates. Why is it, that to students the examination for the Hall is always looked upon with apprehension and a sense of dread, while that for the College is considered as slight,—but because the examination for the former is of a more stringent character? Which requires the greatest amount of preparation—of study, of professional reading and acquisition—the examination for the Hall or the College? All honour be to those to whom honour is due, and in this instance the honour of the improved literary character of the present race of medical men is due to the examination for the Hall, as required by the Apothecaries' Company; and if it be the fact that these are to be despised, because they are mixed up with trade, and are tradesmen, why, then indeed, the professional standing of the tradesman has taken the place of the more polished gentleman; and as it happens sometimes in other cases, the largest amount of worth and literary specific gravity is to be found in the middle classes of the community.

[To be continued.]

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

REPORTS OF CASES ADMITTED UNDER DR. DAVID NELSON.

Extracted from the Clinical Records,

BY W. J. MOORE, ESQ. M.R.C.S., AND L.A.C., RESIDENT MEDICAL OFFICER.

Case XVII.

Case of Eliza Bowen, aged 17, *affected with Phthisis, terminating in Death. Admitted April* 16, 1850.

History.—Eliza Bowen stated, that about three months before admission she caught cold, cough followed, at first dry, but afterwards attended by a tenacious ropy expectoration. She had lost flesh and strength to a great degree, and during the time mentioned had had no catamenial discharge.

Symptoms.—On examination she stated the above symptoms still continued; there was dulness both anteriorly and posteriorly on the right side, but not of a clay-like character; she sweated profusely at night; the tongue coated; tonsils congested, and back part of the throat covered with apthous spots; she spoke hoarsely; bowels were confined; pulse 140; respirations 22; there was dulness and bronchial respiration towards the left shoulder.

Diagnosis.—That there was tubercular deposit in both lungs, but more especially in the right; also a degenerate enlargement of the submucous tissue of the larynx.

Treatment.—To attenuate and expel the ropy mucus, to clean the intestines and improve the appetite, to stop the sweating and relieve the cough, were the first intentions; and she took, Pulv. Ipecac., gr. xxx. post prand; Calomelanos, gr. iv. hac nocte; Infusi Calumbæ, oz. j.; Bismuthi alb., gr. v. ter die ante cibum; Tinct. Opii Camph., dr. j. ter die post cibum; Acid. Sulph., Aromat, gtt. xxx. hora somni. A blister was also applied.

19th.—The tongue was cleaner; she expectorated with more ease; the sweatings had diminished, and she felt her throat better; pulse 128; respirations 26. Cont. med. et sumat Ol. Jecoris Aselli c Ferro dr. j. ter die.

23rd.—The improvement continued, and she spoke less hoarsely; pulse 120; respirations 20. Continue medicine. Blister renewed on the right side.

November 7th.—The cough was more troublesome. Pulse 146; respirations 26. She now took infusion of digitalis, with tincture of muriate of iron; and continued her camphorated tincture, the oil, and sulphuric acid.

10th.—Her cough, sweating, and feverishness had all increased; pulse 120; respirations 22; but on the 14th she was again improved; pulse 108; respirations 32. Continue medicine.

17th.—The cough was still easy; there was little hoarseness; she slept well, but sweated profusely; gurglings were now detected under the right clavicle, not very apparent, but still perceptible under full inspiration or coughing. On this date the expiration by the glass was thirty-two ounces. Pulse 104; respirations 32. Cont. med. et ap. ves.

21st.—The cough was easy, and there was scarcely any expectoration. She slept well, but sweated profusely. The hoarseness had entirely left; the tongue was intensely red at the point and edges, but curiously streaked with two white lines at either side. Gurgling was less. Pulse 104; respiration 18. Cont. med. et ves.

25th.—The cough was easy, and the sleep and appetite not bad. Gurgling still obvious. Pulse 108; respiration 20. Continue medicine.

31st.—The sleep, cough, and sweatings were favourable; but he looked pale, and the tongue was glassy and red, though the gurglings were less distinct. Pulse 140; respiration 26. Cont. med. et sumat Quininæ Sulph., gr. j., ter die.

June 4th.—The symptoms were easy as before, but gurglings were heard under both clavicles, with reverberation under the hammer. Continue medicine.

7th.—She had slept well, but the cough was troublesome during the day. Cont. med. et ap. Emp. Lyttæ. sterno.

14th.—The cough continued troublesome; tongue was pale; the expectoration was slight. The body was reduced nearly to skin and bone, and gurgling cavernous; respiration and pectoriloquy had become very distinct under the right clavicle; the bowels were also relaxed. Pulse 126; respiration 18. She took catechu and chalk, and re-applied the blister.

21st.—She sweated again. The cough was trouble-

some; the gurgling and pectoriloquy were as before. Pulse 113; respiration 20. Continue medicine, and insert a seton on the chest.

25th.—The cough was less troublesome. The seton had not begun to discharge much. The gurgling and pectoriloquy were as before; the former was not of so fluid a character. Pulse 120; respiration 26. Continue medicine.

July 2nd.—She had little sweating, and the appetite was not bad. The green mucous expectoration was streaked with blood. Gurgling now existed in the left side, below the second rib. Pulse 144; respiration 28. Continue medicine. Seton to be removed, because painful.

6th.—The green mucus was full of globular thread-like balls. The body was cold. The pulse at the wrist indistinct, at the carotids 120; respiration 24. Gurglings as before. Int. Ol. Asclli, c. Aliis. Med.

9th.—The cough was very much increased, and one leg was swollen and tender. Continue medicine.

20th.—Both legs were swollen. The cough, pectoriloquy, &c., had increased. The bowels were again relaxed. Apthous crusts had re-appeared. The breath had an earthy odour. Pulse 124; respiration 24. Continue medicine.

23rd.—She spoke in whispers, and had no strength to expectorate. The tongue was cold and pale, and she was disposed to sleep. There was intense cavernous respiration under the right clavicle, but no gurglings on either side. Pulse 130; respiration 36. She died calmly the same night.

Post-mortem.—Both lungs were almost entirely gone. There was a large cavern at the summit, or rather where the summit of the right lung should have been, and numerous small vomicæ in its lower part; the whole of the lowest part being infiltrated with tubercle. A similar large cavern appeared at the summit of the left lung, the rest being greatly infiltrated. The heart was healthy, but very small; liver, large and pale; small intestines were marked with mahogany coloured rings, as if from inflammation.

Observations.—It is most probable that this case was of much longer standing than stated on admission. As may be observed, the pulse and respirations were never in proportion with each other; the former, in fact, may often be increased without any engorgement of the lungs when the heart is small, as in this instance, and the latter may suffer, as they did here, numerous abrupt variations as to number, owing to the alternate obstruction and clearance of the air passages. It may be observed that the pulses and respirations were higher, and the cough worse before the gurglings made their appearance, and were easier after that event had taken place.

Provincial Medical & Surgical Journal.

WEDNESDAY, APRIL 30, 1851.

At the present unusually happy juncture in the proceedings of Medical Reformers, it is needless to maintain that strict silence on the subject which we have thought it right of late to maintain; for as there seems to be an almost unanimous feeling in favour of the recent resolutions of the College of Surgeons, we can scarcely give offence by some slight allusion to them. We have good grounds for believing that the Colleges of Physicians and Surgeons are now in cordial and effective co-operation, and that they will, in the course of next week, jointly seek an interview with Sir George Grey, for the purpose of urging him to put the final stroke to this long-promised measure during the present Session of Parliament.

It will be seen by the annexed memorial that the Council of our Association have not been inactive; they have thought it right to urge upon Sir G. Grey those points in their memorial of May, 1850, which are still left untouched by the College of Surgeons. But, considering that the proposed measure goes so far towards granting all the principles contended for by this Association, it has been thought desirable to throw no stumbling-block in the way of Sir G. Grey, further than to lay the case clearly before him, and then to leave him free to act as may seem best to him. The Council have felt that this is the most prudent course, because in the interviews which have been accorded to Sir Charles Hastings and others, the Home Secretary has evinced a most intimate knowledge of the subject, and an earnest desire to do justice to all parties concerned.

The following memorial is intended to be presented to Sir George Grey, by Osman Ricardo, Esq., M.P.

To the Right Honourable Sir George Grey, Bart., Her Majesty's Principal Secretary of State for the Home Department.

We, the undersigned, on behalf of the Provincial Medical and Surgical Association, beg leave again to address you on the subject of Medical Reform.

Your Memorialists have read with great pleasure and satisfaction, a series of resolutions, which were adopted by the Council of the

College of Surgeons on the 19th and 24th of March, and which are in the main, in accordance with the principles laid down in the Memorial which they had the honour of presenting to your notice on the 2nd of May, 1850.

Your Memorialists are grateful for the liberal concessions which have been offered to their representations, and have no hesitation in accepting these resolutions as the basis of a final settlement of the question of Medical Reform. But at the same time they would call to your recollection the nature of the Memorial above alluded to; for if the second paragraph of that document is compared with the resolutions lately submitted to you by the Council of the College of Surgeons, it will be seen that the elective power is now intended to be confined to the Fellows, whilst your Memorialists have always contended for its extension to all Members of respectability and good character.

But your Memorialists would most anxiously endeavour to impress upon you the necessity, not only of conferring new charters upon the Colleges of Physicians and Surgeons, embodying the proposed reforms in their constitution, but also of carrying out the third paragraph of the above-named Memorial, which is as follows:—

"That after such remodelling of the constitution of the existing colleges, it is also desirable to appoint a joint board of physicians and surgeons, with the aid, if necessary, of competent examiners in midwifery and pharmacy, who shall examine every candidate desiring to enter the profession, in medicine, surgery, midwifery, and pharmacy, and shall, on his passing such examination to their satisfaction, issue a diploma or licence to practise all or any of these branches of the profession in any part of her Majesty's dominions."

Your Memorialists consider it a matter of sincere congratulation that you now have it in your power without injustice to any party, to put an end to this long protracted state of confusion and discord in their profession, and they beg to assure you, that though they hold strong opinions upon the propriety of the principles which they have alluded to, and also upon some others of minor importance, believing them to be based upon justice and expediency, yet they would gratefully receive any modification from your hands, which you may be pleased to consider as the most desirable for all parties.

We have the honor to be, Sir,

Your obedient Servants,

CHARLES HASTINGS, M.D.,
PRESIDENT OF THE COUNCIL.

J. P. SHEPPARD, SECRETARY.

We believe that at no former period has there ever prevailed so sincere a desire among the authorities of both our Colleges to do justice to the claims of the provincial practitioners; and we are of opinion that under the intended arrangements there will be no impediment, excepting that of distance, (which is daily becoming less and less in its effects,) in the way of their taking the same standing in their respective Colleges as would be accorded to their scientific attainments were they inhabitants of the great metropolis. It may be said, and with great truth, that this position has only been gained at the point of the bayonet; but let us remember that many of those who are now in power were formerly fighting in the same ranks with us, and have been mainly instrumental in altering the opinions of their fellow-councillors. We trust, therefore, that as the year 1851 is to witness an harmonious meeting in the cause of general science and manufactures, it will be equally signalized by a cessation of strife in our hitherto divided profession. We shall find quite enough to do to maintain an equal progress with the grand march going on in other and collateral branches of science; and we may then hope to regain some of that respect for our art which has been frittered away by an undignified squabbling among ourselves.

Reviews.

Memoir on the Influence of Hypertrophy and Dilatation, on Diseases of the Heart, and on some points in their Diagnosis and Treatment. By Dr. HALLIDAY, Douglas. Edinburgh: Sutherland and Knox.

THE object of the present pamphlet, which is a reprint of papers published in a monthly contemporary, is to point out the importance of hypertrophy and dilatation, more especially the latter, in diseases of the heart, and to exhibit the fact of their frequent if not invariable coexistence. The author's intention is carried out by the detail of cases under four sections, embracing respectively—1st, Hypertrophy and Dilatation; 2nd, Aneurism of the left Ventricle; 3rd, Contraction of the Valves; and 4th, Incompetence of Valves.

In the course of his observations other questions connected with heart disease, meet with careful consideration, as for instance, the diag-

nosis of aneurism of the ventricle; the physical signs of mitral contraction, &c.

In reference to the first of these sections, after narrating two cases, he observes:—

"In neither of these cases did there exist any physical sign which is not familiarly known to arise in other forms of disease of the heart. In both cases there existed a murmur with the first sound, which, however, was not to be distinguished from the murmur of mitral incompetence. In one case, from the appearances described, there can be little doubt the mitral valve was incompetent, and gave rise to the murmer in question. In the other, the *post-mortem* appearances did not indicate incompetence of the mitral valve; and the endocardial murmur with the first sound at the apex, must be attributed to the aneurisms in that situation. The only peculiarity noticed in the murmur was its greater distinctness at the base of the heart than is usual with murmurs loudest at the apex. This, however, does occasionally occur in murmurs from mitral incompetence; and a circumstance so trivial and uncertain is really unimportant.

"It has been suggested, that under possible circumstances, a double "to and fro" murmur might occur in aneurism of the heart. I am not aware that a double murmur has ever been observed; it at no time existed in these cases; and the form of the sacs as well as their narrow orifice, appeared fitted to create the double murmur, if its existence were possible:—A double "to and fro" murmur would perhaps assist in distinguishing these aneurisms, while it is impossible to distinguish the single bellows murmur, having its seat in the orifice of an aneurism, from one having a very different source.

The other physical signs in these cases were identical with those which are known to characterise hypertrophy and dilatation,—the latter especially is known to preponderate from the feebleness of the cardiac impulse, the horizontal extent of the præcordial space dull on percussion, the softness of the radial pulse, and from the mutual relations of these signs to each other; and these signs must of necessity arise in cases, such as the present, in which the following conditions existed:—An extensive degeneration of the muscular substance of the heart; an unyielding and unwieldly state of the organ arising out of the rigid and deformed state of its walls; and above all, the increased capacity which must result even from partial dilatation."

The value to be attached to the character of the pulse in cardiac disease is thus succinctly stated:—

"The various changes which the pulse undergoes are more intimately related to changes of the muscular substance, than to valvular lesions. There are conditions of the pulse which depend only upon valvular disease; but these may be limited to two—the small pulse of mitral or aortic contraction, and the quick diastolic pulse of aortic regurgitation.

The *visible* pulse is not always an abnormal condition; but even in its higher degrees, it has no relation to valvular disease. *Irregularity* has been regarded as significant of mitral incompetence but it frequently exists in cases where there is no valvular disease; and it occurs with mitral incompetence, in such circumstances as lead me to believe that it arises only in consequence of superadded dilatation.

Want of *synchronism* of the arterial pulse with the heart-beat has a doubtful connection with valvular disease; it does not occur except in conjunction with more or less dilatation; and I have met with it altogether apart from valvular disease.

Delay of the radial pulse has been stated to depend upon incompetence of the aortic valves; I do not think such is the fact. The radial pulse is naturally more or less posterior to the hearts impulse; and the interval may vary within the limits of health; besides, from the very nature of the thing, it is difficult or impossible to affirm in a particular case that the *degree* of delay is abnormal. From my own observations, I am satisfied that an appreciable increase in the delay of the arterial pulse is very rare; and it does not arise in such a proportion of cases of aortic imcompetence as to indicate any relation between them."

On the whole, the author has afforded an useful contribution to the literature of cardiac pathology; but it scarcely in our opinion requires a circulation separate from the source in which it originally appeared.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

March 6th, 1851.

MR. CARTER IN THE CHAIR.

Diseased Bladder and Kidneys from repeated formation of Calculus.—By Mr. Savage.

Steven C., aged 61, a moulder by trade, of full habit of body, who has drank to a considerable extent, has been subject for the last fourteen or fifteen years to the frequent passing of urinary calculi, accompanied at times with considerable inflammatory action. About four years ago he had every symptom of calculus in the bladder, but on passing the sound, I failed to detect one. The same result was obtained by two or three medical friends. From that time (*i. e.*, four years ago) to January last, I lost sight of him, but have understoood that about three years since he was sounded by a gentleman who was particularly anxious about calculi, but who then failed to discover one. I believe since then he has been quacking about from one person to another, and trying every nostrum recommended. In January he came under my care for pneumonia of the right lung, under which he sunk before the end of the month; at this time he was very frequently passing a quantity of pus and blood with his urine, and I understood this had been the case for some months.

I succeeded in obtaining a limited *post-mortem*, being confined to the abdomen. The liver was much enlarged otherwise healthy; some old adhesions of the intestines not very firm, indicating slight peritonitis to which he had at times been subject; the right kidney was com-

pletely disorganized, containing a large cavity partly filled with pus; the ureter much enlarged and thickened, in which a large calculus was firmly impacted; the left kidney very much enlarged and hypertrophied, with marks about the pelvis where calculi have lodged; the ureter enlarged so much, as to allow of the easy passage of a finger; the bladder much softened, thickened, and resting loosely in it a large phosphatic calculus. This formed the extent of the *post-mortem*, and perhaps it is interesting to inquire whether the very large calculus found in the bladder has been formed within the last four years, or a nucleus existing at that time. I think so many of us could not have failed to detect it on passing the sound.

Red Ramollissement of the Cerebrum, with rather peculiar symptoms.—By Mr. Bangham.

— Hill, aged 39, died of an apoplectic attack, of seven hours' standing, with paralysis of the left side. His habits temperate and industrious. He had always been healthy until about two months ago, when he began to complain of headache, dimness of sight, and giddiness, in which state he fell several times. He had, however, slight symptoms of head affection for six months, observed by his mother though not by himself. He continued to work with little interruption till about a week before death, and on the day previous he appeared to his friends in better health than usual. The above-mentioned symptoms occurred in fits; the pain was often very severe. The attacks were always followed by drowsiness.

Mr. Carter saw him once only (as a dispensary patient) about seven hours before his fatal attack. He was drowsy, and complained of great pain in his head, for which he had a handkerchief tied round it. He was always in this state on the cessation of the fits; and no particular notice was taken of it. Had lost his appetite for two or three days, with nausea, and complained of feebleness and weakness from not having taken food.

Sectio-cadaveris.—The vessels of the pia mater much distended, but no unusual vascularity of the brain, which was firm and healthy throughout, excepting the posterior lobe of the right hemisphere, which was much softened and vascular, and contained two or three small coagula or ecchymoses; a small quantity of clear fluid in the ventricles. The falx major was wanting between the anterior lobes, which were closely connected.

Chronic Peritonitis, with great Contraction of the Meso-Colon and Mesentery.—By Dr. Fletcher.

Thos. Yates, aged 59, a lime-burner, admitted into the hospital January 3rd, 1851, labouring under effusion into the peritoneal sac, without anasarca; enlarged superficial veins of the lower portion of the abdomen; there was fluctuation and dulness upon percussion all over the abdomen, but on pressing firmly upon the abdomen, a dry crepitation was felt on rubbing the parietal and intestinal surfaces of the peritoneum together. He took small quantities of mercury and diuretics, but the abdomen increased in size, and his general health failed. He died from asthenia on the 24th of January.

Post-mortem examination July 25th.—Head: Brain healthy. *Chest:* Heart and lungs healthy. *Abdomen:* The peritoneum generally thickened, and opaque; over the surface of the liver, spleen, and pancreas, it was thickened, and contracted these organs, which, in their proper substance were healthy; over the intestines it was thickened, and also in the mesentery and meso-colon, which were very much contracted, the mesentery so much so as to draw the small intestines into a bunch against the spine; the thickened mass contained fibrin; within the layers of the mesentery, and at its root, where it was very abundant. I have examined it by the microscope, and find nothing more in it than fibrous or condensed cellular and fatty tissues.

It is worth observing, that although in this case the intestines were so far from their natural condition, there was at no time any deviation from health in their functions. He did not suffer from constipation at any time.

Softening of the White Matter of the Cerebellum.—By Dr. Fletcher.

Charles Walker, aged 11, admitted into he Hospital, December 7th, 1850. A thin weakly-looking child, but had enjoyed good health until about three months ago, with the exception of rather profuse discharges from the ears. One of the first symptoms noticed by his friends was, that when in motion, he appeared to have difficulty in stopping himself, so that he would often strike his head against any object that came in his way, and when he stooped he felt giddy; and at this time he frequently complained of giddiness in the head, and his memory and appetite fell off; he was sick in the mornings. His gait was noticed to be peculiar, as if he had a difficulty in balancing himself, and he staggered greatly. At three months old he had convulsions. Family healthy, but the grandfather and grandmother died consumptive. On admission, his chief complaints were pain and giddiness in the head. His look was lively, but the expression of his eyes somewhat vacant when not addressed by any one. His answers to questions perfectly coherent. He had no loss of sensation or motion in any part of the body, with the exception that ordinarily he scarcely ever closed the lids of the left eye. When told to shut both eyes he was observed to be able do so. He walked with his legs far apart, and evidently felt unsteady, and welcomed in consequence any artificial support. When told to walk up and down the room he was unable to stop at the door, but struck his head against it, which he always carried a little in advance of his body. He made no complaint of thirst but it was stated that he was sometimes sick.

17th.—A seton to be inserted in the nape of the neck.

19th.—Complains of sickness and of his mouth being sore by mercury prescribed. In other respects he is about the same as on admission. Pills ordered to be stopped. About half-past nine in the evening after being unusually quiet for the two or three hours preceding, he suddenly lost sensibility and breathed stertorously. When seen, his face had become of a bluish tint and there was foam on his lips. The heart was acting with vigour, but the breathing had nearly ceased. A few minutes afterwards he died.

All the organs healthy but the cerebellum, pons varolii, and medulla oblongata. A large quantity of

fluid in the lateral ventricles; part of the white substance of the cerebellum, the medulla oblongata, and the pons varolii, was considerably softened. In the cerebellum the softening existed chiefly in the left lobe, and extended into the middle; it was so soft that it was of the consistence of thick cream, and was quite pulpy to the feel; and the cerebrum fluctuated under the fingers, as if it contained pus. Under the microscope it was seen to consist of the broken-up nerve-tubes and clear cells, and compound exudation-cells in a clear fluid. Near the origin of the optic nerve of the same side was a small duct, which contained a small firm substance, which appeared to be a condensed and hardened tubercular debris.

Puerperal convulsions: Death. Gall-stones in the gall-bladder; great General Dilatation of Gall-bladder, and Hepatic Ducts, without any apparent cause.—By Dr. Russell.

February 10, 1851.—I was requested by Mr. Welch to visit Mrs. Yates, age 25, she had had four children. On the 5th she was seized with severe epigastric pain, passing through to her back; believing herself in labour, she sent for a midwife, who in turn, desired her to summon a doctor. Mr. Welch found her complaining of this severe pain, with great dyspnœa. He ordered some calomel and opium, to be followed by castor oil. The symptoms were soon relieved considerably, without the bowels acting. She improved considerably, and on the 7th was delivered of a healthy living child, after an easy labour, without hemorrhage. The placenta came away naturally. On the 8th she seemed doing very well; but on Mr. W. calling on the evening of the 9th, he found that at three A.M. she had had a fit of an epileptic character; she had, however, perfectly recovered from it. The lochia had become suppressed, and the urine was very scanty throughout the day; the milk had appeared naturally. This morning (10th) at 3 A.M., having become very restless, she complained of violent pain about the small of the back, passing to the epigastrium; she fell into another fit from which she recovered, but with incessant desire to micturate, getting off bed constantly without passing any urine; this continued till five, she remaining tolerably sensible; another fit then came on and returned two or three times in succession, leaving her insensible. He ordered ammonia. Two P.M. Feb. 10th, I found her lying on her back, just conscious of being called to or of being moved; pupils dilated somewhat by light; surface rather hot, but easily lowered; pulse, quick, very easily extinguished; breathing, rapid; sounds of heart very feeble; she was pallid, excepting that her skin and conjunctiva had a jaundiced tinge observed this morning; she appeared in a very anæmic condition, and thin; she had passed a very offensive evacuation, without bile, under her; the uterus was large, very hard, not tender. Wine, ammonia, vesicatorium, nuchæ.

She is a tailoress, living in a miserable house, in a very close court, and very poor. Her husband could never induce her to take any exercise, she preferred sitting still. For the last three years she has been subject to sudden violent seizures of pain in her epigastrium, which would "sometimes take her senses away." They seldom lasted long, and she has never been laid up with them for longer than a day; has never passed gall-stones; nor had jaundice; nor any other complaint. Of temperate habits. She died two days afterwards (February 12th) without having made any marked improvements, or presented any fresh symptoms of importance. She had no return of the fits, but continued quite insensible. She took the wine abundantly. The jaundice deepened considerably.

Sectio-cadaveris 60 *hours after death.*—Body, deeply jaundiced; blood, very poor and scanty; brain, healthy; chest, healthy; the liver seemed healthy, not larger than usual; the gall bladder had its walls unusually thick; it contained thin brownish bile, and 5 gall stones, nearly spherical, with the surface somewhat formed into facets, their diameter half an inch; they were formed (externally) by an aggregation of small stones a little larger than hemp seeds, closely united; they were composed chiefly of cholesterine. On dividing the liver, brownish bile was seen to flow in streams from all parts, from the open mouths of large branches of the hepatic ducts, the size of a goose quill; these open mouths appeared in all parts, separated, however, from each other by considerable distances; on tracing them up, this great dilatation continued to their termination, or nearly so; they presented throughout the size of a goosequill, and closely resembled dilated bronchi; the trunk of the hepatic duct was of the capacity of a full-sized vena portæ, and its two primary divisions hardly smaller; the cystic duct was somewhat smaller, though greatly dilated; the dilatation was less in the common duct, and it contracted before its termination in the intestines; duodenum, healthy. The coats of these dilated ducts, were only thick in proportion to their capacity; the common duct was the only one which had any appearance of hypertrophy; their interior was healthy; all were filled with bile. The tissue of the liver was very soft, like the condition of the organ in advanced typhus, without the congestion; in many parts no appearance of the lobular structure remained; the envelope of the liver was healthy We could not discover any explanation of this dilatation of the hepatic ducts. The stomach and duodenum contained a brownish fluid, from its colour seemingly tinged with the bile; below there was no bile in the intestines, merely a coating of tawny mucus. Mucous membrane of the stomach very coarse. Kidneys were large, and deeply stained with bile. The tissue healthy by the microscope. The exemption of the malpighian bodies from the bilious tinge, which had dyed the whole of the epithelial structure was very striking, and afforded strong proof of the absence of cells from the capsules as asserted by Bowman. The uterus was perfectly healthy; it contained a large recent clot.

In connection with the apparent inconsistency of the absence of jaundice, with the existence of previous obstruction to the exit of bile, sufficient to cause such extensive dilatation of the ducts, Dr. Fletcher, remarked, that the lower class will often answer in the affirmative when asked if they have ever been yellow, when they will deny having had jaundice; in this case the question had only related to the presence of jaundice. Dr. Russell stated he had been favoured by Dr. Budd with his opinion, that in this case the obturation of the primary ducts was probably occasioned by the entrance of gall-stones on former occasions.

Means of Solidifying Foot Prints.

It is often a matter of great importance in medico-legal investigations to preserve an accurate mould of foot prints; for this purpose M. Hugoulin (*Annales d' Hygiene*) recommends the following plan:—An iron plate, supported by bars, is so placed as to be about three or four *centimetres* above the mark to be solidified, and upon it live coals are to be placed so that heat may radiate to the subjacent soil. When this has become heated to about 100°C, *stearic acid*, reduced to impalpable powder, (by previously dissolving it in its weight of alcohol, and then, having added abundance of water, evaporating,) is to be dusted over it through a fine hair seive, so as to form an uniform layer. This, falling as a snowy dust, cannot by its weight injure the impression, and is indeed dissolved and absorbed as soon as it touches the soil. It is continued until the earth has become too cold to dissolve any more. After a sufficient time has been allowed for it to have become completely cold, the earth is mined round at some distance so as to raise the entire mass in a single piece, cutting afterwards carefully away the superfluous soil. After reversing it on several folds of linen, and surrounding it with a case, plaster is allowed to run in between the case and the reverse of the impression, so as to ensure complete solidity to it. If the soil is muddy or marshy, before commencing these operations, a trench should be dug around, into which plaster is to be introduced, which, on solidifying, will absorb much of the moisture, after which the whole mass may be exposed for some days to the sun and air before commencing to act upon it. M. Hugoulin says this plan is applicable to the most shifting soils, as sand, &c., and indeed to all except snow.

Case of Fatal Hæmorrhage from the Female External Genital Organs.

Cases are not unfrequently brought before the courts of justice in this country, in which a fatal hæmorrhage has resulted from the female external organs being wounded by cutting instruments; but such hæmorrhage has less commonly occurred from a contused wound. In an instance related by Dr. Evrard, (*Ibid*,) the wound resulted from a kick with the boot of a brutal husband, armed externally with enormous projecting nails. The woman, previously in good health, walked a short distance after receiving the injury, bleeding all the way, and was dead when assistance arrived. The body was found quite pale and exsanguineous, the heart and large vessels being very empty, and no effusion into any internal organ discoverable. A large lacerated wound in the labium was discovered, the finger freely passing to the horizontal ramus of the pubes in one direction, and towards the cavity of the pelvis externally to the vagina in another.—*British and Foreign Medico-Chirurgical Review.*

The Galvanic Poultice.

This name is given by M. Recamier to a method of employing galvanism locally. The application consists of cotton wadding containing alternate layers of zinc and copper plates. The whole is covered by a bag, one side of which is water proof. The permeable surface is placed next the skin. The galvanic current is developed by the perspiration.

Treatment of Displacements of the Uterus.

This subject has been investigated by M. Valleix, who records his observations in the *Bulletin de Géneral de Therapeutique*, (*Medical Times*, April 18.) He has satisfied himself that the various flexions and versions have really a prejudicial effect on the female health. The method of treatment recommended by him is the use of a modification of Dr. Simpson's intra-uterine pessary. The treatment is to commence with the daily introduction of the uterine sound for the purpose of dilating the neck of the organ. When the sound passes with facility, and without inflicting pain into the uterus, then the pessary is to be introduced. "I have never seen," says M. Valleix, "a single accident from its employment, and the cases in which I have obtained complete success are numerous."

The modifications in the pessary of Professor Simpson, proposed by Valliex, are a great reduction in the size of the disc to which the uterine branch of the instrument is fixed, a joint between the uterine and vaginal branch, a vaginal screw, by which the latter branch can be elongated at pleasure. M. Valleix's instrument is made by M. Charrière, of Paris.

Chloroform Injections in Gonorrhœa.

Injections of chloroform are recommended by M. Venot, (*Union Médicale,*) in the abortive treatment of gonorrhœa; they are productive, in the first instance, of great burning, subsequently of a feeling of cold. He states that used before the second day, this plan is almost invariably successful.

[From what we know of the pain attending the application of chloroform to the skin, its contact with a sensitive mucous membrane must be too intolerable to admit of its general use.—Ed. P. J.]

Ileus; Cure by "Firing."

The following is not the least marvellous of the cases which from time to time appear in the French Journals. The case is translated in the *Medical Gazette*, from whose pages we quote:—

"A peasant of Saussaye, Canton of Elbeuf, about 30 years of age, was suddenly attacked in the afternoon of October 24th, 1850, with most acute pains in the abdomen, followed by nausea, eructations, and vomiting. He had been in perfect health in the morning. The abdomen was soft, and no rupture existed. The patient pointed out a spot near the umbilicus where the pains attained their maximum intensity, and whence they irradiated towards the pelvis. Various means were unavailingly employed to relieve the agonizing sufferings,

which were distressing to behold. The symptoms rapidly got worse, the vomiting became stercoraceous. Three days and nights were passed without sleep or cessation of pain, and without the retention of any nourishment on the stomach. On the evening of the 28th October, determined to make one last effort, Dr. Hervieux summoned the aid of Dr. Justin, and placed the patient under the influence of ether. The relief which followed lasted only a quarter of any hour, and the feebleness of the pulse restrained a second exhibition, lest the patient should have died under its exhibition. At this moment the thought occurred of trying Mayor's hammer. Four applications were made at the point where greatest pain was experienced, each application was not less than for a minute. Instead of confining himself to the application of the hammer moistened in boiling water, some force was used in applying the hammer on the abdominal surface, so that it might possibly exert some direct action on the viscera. The pain that was caused was so great that it required several persons to hold him during the operation. This pain was, however, quickly followed by an indescribable sensation of relief. At the expiration of some minutes there was an escape of gas from the intestines, which seemed to be the re-establishment of the intestinal circulation. This escape of gas became more considerable, and was followed by an abundant stool, proving that the obstacle was removed. On the following day the patient was quite well, and asking for food.

"It is doubtful, (Dr. Hervieux observes,) if any other case be on record of a remedy so manifest, instantaneous, and permanent, especially by means so harmless and accessible."

[The "Marteau Mayor" is the French prototype of the "firing" apparatus of Dr. Corrigan, since alluded to by Dr. Day in his "Treatise on the Diseases of Old Age."—Ed. P. J.]

General Retrospect.

ANATOMY AND PHYSIOLOGY.

On the Structure of the Mucous Membrane of the Appendix Vermiformis and Colon.—By John Neile, M.D.

The mucous membrane of the appendix vermiformis differs materially from that of the colon in the arrangement of its capillaries. When the mucous membrane of the colon is properly injected, and deprived of its epithelium, it is seen to be regularly studded with the mucous follicles of Leiberkuhn, all much of the same size and shape; the orifices are formed by a ring of one or two capillaries, which gives the whole surface an appearance very similar to that of ordinary coarse lace. The depth of these crypts is sufficiently great to render the term tubule applicable to them, and unless the epithelium is carefully removed from these tubules by washing, or the preparation dried, so that the epithelium becomes transparent, the capillaries forming the parietes of the crypts or tubules are not evident. The regularity and number of these crypts are sufficient to render the colon distinguishable from the stomach, although numerous high anatomical authorities state that no difference exists between the mucous membranes of these important organs; but when we accurately consider the forms of the orifice, the depth of the crypt, together with the arrangement of the capillaries forming the orifices of the crypts, and the intervening spaces, the difference between the mucous membrane of the stomach and the colon will become evident even to the superficial observer.

The appendix vermiformis exhibits a different arrangement of its capillaries from the colon; the crypts are variable in size and shape, and the distances between them are by no means uniform. The interstices between them are formed by a beautiful interlacement of capillaries which presents an extremely regular appearance.

[The same observer has described the anatomy of the mucous membrane of the stomach in the *American Journal of Medical Sciences* for January, 1851, accompanied by an illustration of the different appearances of that membrane in the cardiac, middle, and pyloric portions. The following is his description:—]

The surface of the mucous membrane presents different appearances in different portions of the stomach; this fact not having been sufficiently appreciated by observers, we consider as one of the sources of error in the ordinary descriptions of this organ. By far the larger portion exhibits various modifications of the honeycomb structure, the cells are large and polygonal in some parts, in others they are smaller, deeper, and rounder; the ridges between these cells are formed of one or more convoluted capillaries, and this arrangement of capillaries is particularly evident in the rugæ. The walls of these cells or pockets are formed of a network of capillaries, which subdivides each cell into smaller ones; these cells are what are ordinarily called the orifices of gastric glands, and the subdivision in the bottom of each cell corresponds with the described orifices of tubuli. In the antrum pylori the structure is modified, the ridges between the cells become larger, more elevated, and as we approach the pyloric orifice, *conical villi* make their appearance; these villi are more numerous and larger towards the pyloric valve, so that fewer of the angular or polygonal cells are visible in their interstices; they are not so large as the villi of the small intestine, but in other respects their external appearances are precisely similar. When well injected, they seem to be composed of capillaries, closely united by a basement membrane, and forming a pyramidal projection.

There may be said to be three different appearances presented by the microscopic examination of the injected capillaries of the mucous membrane of the stomach when deprived of its epithelium:—1st, the convexity of a large ruga will have a comparatively smooth and even appearance formed by convoluted and intertwining capillaries; 2nd, any other portion excepting the antrum will exhibit cells or alveoli of different sizes and shapes, separated by ridges of various thickness, and these ridges are composed of capillaries

arranged in the same manner as the rugæ; 3rd, in the antrum pylori there are *conical villi*, and cells exist in the interstices and at their bases.

That the main point which we wish to prove may be understood in a few words; we would simply state that we consider the capillaries arranged in the form of "ridges, cells, and *villi*." The question may now arise, whether this description in any manner deviates from those ordinarily given in the standard works of the day? We consider that it does, particularly with reference to the villi, the existence of which, in the stomach, we wish fully to establish by description and demonstration. It might be asked, whether the term *villous* has not consequently been used with reference to the mucous membrane of the stomach? Unquestionably it has, though in a vague and loose way, as indicating a smooth, velvety surface, but not as implying a vascular, papillary projection to which the term *villus* is applied in the intestine."—*Philadelphia Medical Examiner*, February, 1851.

PRACTICAL MEDICINE.

Treatment of Aphonia by Stimulating Inhalations.—By Dr. Pancoast.

The form of aphonia, here alluded to, is that following an ordinary cold, without leaving any perceptible organic lesion in the pulmonary apparatus. The voice is reduced to a faint hoarse whisper, distinguishable only at the distance of a few feet; and a continued attempt to talk, though it gives no pain, becomes quickly attended with a feeling of fatigue, as though there were some obstruction to the passage of air through the larynx. In breathing merely, there is little or no difficulty; as the individuals are capable of undergoing considerable exertion without any unusual signs of fatigue. Having had an opportuniy, several years ago, of observing the movements of the vocal chords, in a person who had attempted suicide, and was left with a cicatrized wound opening into the ventricles of the larynx, Dr. Pancoast watched with great interest the play of these vocal chords, which were fully exposed to view, and was astonished at their frequent, varied, and extensive movements. From the evidence he obtained with regard to their motion, he was led to infer that this form of aphonia arose from a partial paralysis of the intrinsic muscles of the larynx, to be cured by stimulating them to action. His first case occurred eight years ago. The patient was a healthy young country girl; the aphonia had lasted for six months, resisting all treatment. She was made to inhale chlorine, gradually liberated from chloride of soda or lime, by very dilute hydrochloric acid, in a common glass retort. The inhalation was continued for some minutes, and repeated two or three times a day according to the degree of irritation produced in the throat and larynx. From the first trial the patient's voice improved, and in three days had become nearly as strong as ever. Two months after her return to the country, another cold was followed by an attack of aphonia, which also yielded to a few inhalations of chlorine vapour. Dr. P. has since treated a case in a medical practitioner, who had tried, among other remedies, repeated applications of strong solution of lunar caustic, without any good effects. The voice was restored to its natural strength in a week or ten days. He suggests that care should be taken that the chlorine be not developed too rapidly. He believes that it acts merely as a local stimulant, and that iodine, or any other exciting vapour, would produce similar results. —*Transactions of American Association.*

On the Efficacy of Cod-liver Oil in Phthisis.—By Dr. Levick.

Fourteen cases are recorded with these results. In the first there was increase of benefit and strength without change in the local disease. In the second the disease was far advanced, but its progress was arrested for a time. The third case was prolonged by the use of the remedy. In this instance diarrhœa was present. Case the fourth was a striking instance of the happy effects of the oil. Cough, emaciation, &c., all successively disappeared under the sole use of the medicine. In this case there was decided improvement in the local disease, as shewn by the physical signs. In two other cases marked improvement occurred under very unpromising circumstances. The seventh case showed no benefit, though the patient thought the contrary. Case eleven was most gratifying. The age of the patient, advanced state of the disease, and the size of the cavity, gave little hope; but the man recovered sufficiently to resume his work. Case fourteen was as favourable; the remainder derived no benefit.

The author remarks that he has seen nothing to warrant the belief that cod-liver oil will *cure* consumption. No case has come under his notice in which the disease, as declared by physical signs, was removed. But considering that in all the cases reported the disease was advanced, and that a cavity existed in six, the effects were most gratifying. Under ordinary treatment no benefit could have been anticipated.

The oil used by Dr. Levick was of two kinds, pale and brown. He prefers the pale variety as especially efficacious, and less offensive. He observes justly that it is highly important that the value of this remedy should be determined, as exaggerated impressions of its worth are apt to be followed by disappointment. In his own cases most of the patients increased in flesh, weight, and strength; and in most the cough and hectic diminished. In no case was pulmonary hæmorrhage or congestion to be traced to the use of the oil.—*American Journal of the Medical Sciences*, Jan. 1851.

SURGERY.

On the Treatment of Anasarca by Puncturing the Legs.—By John Hilton, Esq.

Mr. Hilton has presented a communication to the Royal Medico-Chirurgical Society, (March 25th,) with the object of suggesting the more frequent employment

of puncturing the legs in appropriate cases of anasarca depending upon visceral disease. After referring to the use of this remedy, without due precautions being observed, and the very probable mischief likely to supervene in such a case, the author states that his experience has convinced him of the great relief which anasarcous patients manifest when the fluid is allowed to escape from the areolar tissue of the body through artificial openings; and that when the operation has been done with caution and due consideration, it is not usually followed by unfavourable consequences. The instrument recommended to be employed (of which there was a drawing sent round) may be described as a very narrow, sharp-pointed lancet. Two, or sometimes four, punctures should be made by it in the outer side of the thigh, by passing it obliquely through the subcutaneous areolar tissue, so as to reach, but not to wound, the fascia covering the muscles; the limb, or limbs, if both have been punctured, to be immediately wrapped separately in warm blankets, these to be renewed often enough to prevent the limb becoming cold or chilled by the accumulation of the exuded fluid around it. Should the delicacy of the patient's skin, or any apprehension regarding the chemical character of the effused fluid, lead to the supposition or probability that the skin might become excoriated by the fluid running over it, then it is advisable to use capillary conductors in the form of worsted threads, so arranged as to pass over the punctures, and thence into proper receptacles, so as to keep the limb dry. After alluding to the continuity of the areolar tissue of the whole body, and expressing his belief that the infiltrated areolar tissue within the body, as well as that of the exterior, may be drained effectually by making punctures in the lower extremities, the paper explains the method of relief which is obtained, viz., that by freeing the subcutaneous areolar tissue of fluid, room or space is given for the external veins to become distended with blood, so as to relieve internal visceral congestion, and prevent effusions of fluid into the serous membranes, which produce great distress and death. The author states his conviction that such fatal serous effusions are mainly the result of a passive congestion in the internal veins, and not of an inflammatory condition of the serous membranes; and that the surest method of preventing the occurrence of internal dropsy, is to allow the venous congestion to take place upon the exterior of the body, where it produces a dropsical state of the subcutaneous tissue, and from which the fluid may be removed by artificial punctures through the skin. One of the chief reasons adduced for believing that such dropsies, whether within the body or upon the exterior, are the effect simply of venous congestion, is, that they may be imitated, after death, by injecting any afferent blood-vessel with water, and intercepting its return through the efferent blood-vessel, when escape of water occurs through the walls of the blood-tubes, and induces a dropsy of the parts. Other observations were made, explaining the *rationale* of the relief afforded to the heart, lungs, brain, and spinal marrow, by puncturing the legs in cases of anasarca. Towards the conclusion of the paper the author says, that having seen, in very numerous instances, extreme relief given to anasarcous patients by puncturing the legs in the way described, and only in a few examples any important inconvenience, and still more rarely, if proper precautions have been taken, any danger from it, except as a part of the patient's general condition, he feels himself justified, from personal experience, in recommending its more frequent adoption, in appropriate cases, than usually obtains in practice.

[We cannot agree with the author in his preference of a lancet for puncturing the legs; we have found such punctures to be more readily followed by erythematous inflammation than those made with a curved needle.—Ed. P. J.]

Ascarides treated by Kousso.—By Dr. Bushnan.

Dr. Bushnan narrates the following case, shewing that the new remedy, the Kousso, is destructive to the thread-worm as well as to the tænia:—

Three weeks ago Mr. N., a gentleman in a public office, applied to me. For more than two years he had suffered from thread-worms, and a host of anomalous symptoms. During that period not only had he used turpentine lavements, but had further been exposed to all the regular routine of practice generally adopted in similar cases; calomel, drastic purgatives, oleaginous vermifuges, salt and water, rue, worm-seed, and pomegranate, were ineffectually administered. The worms are always enveloped in a great quantity of viscid mucus, and thus were they probably sheltered from the action of the turpentine.

I determined to try kousso, and I believe I now record the first instance of its use for the removal of ascarides. I directed my patient to take a dose of castor oil at bed-time, and in the morning, when the purgative had freely operated, to inject an infusion of kousso—oz. ss. ad oz. viij.—into the rectum, and to take the same quantity by the mouth. He did so with the happiest results. A great quantity of worms came away. He has had no return even of the itchiness, from which he had previously suffered much, and now assures me he feels "quite a new man."—*Medical Times*, March 29.

MIDWIFERY.

Substitute for the Speculum.—By Dr. Inman.

Dr. Inman suggests, that as the speculum is an indecent instrument, caustic applications should be made with a piece of sponge tied to a stick, which has the further advantage, that the patient may operate upon herself.—*Medical Gazette*, Feb. 28.

[We do not doubt that in some cases this simple contrivance may be fouud useful, but we are just as certain that in the treatment of severe cases of granular "*ulceration*," (we will omit the term when we hear of a better,) it would be as wise to endeavour to apply the caustic without ocular aid, as for the surgeon to shut his eyes when he takes up an artery.—Ed. P. J.]

Medical Intelligence.

SESSIONAL REPORT OF QUEEN'S COLLEGE, BIRMINGHAM.

In accordance with the following regulations, issued by the Council of the Queen's College, in Birmingham, namely,—"That the professors shall keep a book specifying the times of attendance of each student, such book to be laid before the Council at their monthly Boards; that previously to the commencement of every lecture the professors shall call over the names of the students, and shall forward to the warden, seven days before the end of each term, their registers of attendance, or a terminal report of the attendance, conduct, and progress of *each student* in their respective classes and departments, from which details a general report shall be drawn up by the warden, and submitted to the Council, and copies of the reports *on each student* shall be forwarded by the warden to the parent or guardian *of each student*." A most elaborate statistical report has been presented by the Rev. Prebendary Gray, the warden, which cannot but prove highly gratifying to the friends of the Institution and to the public, and will afford a satisfactory proof of the earnest endeavours of the Council to maintain regularity and discipline in every department. Our space will only permit us to give a short abstract from the report. It appears that ninety students have been inserted on the register of the medical department, of which number sixty students have been in attendance at the medical and surgical practice at the Queen's Hospital during the past session.

Collegiate Discipline.—Of the resident students in the senior department, Messrs. Wilkinson, Franks, Waller, Day, Webb, and Bussigny were reported as *very regular and satisfactory* in regard to Collegiate discipline and attendance at the chapel; of the resident students in the junior department, Messrs. Down, Coathupe, Bond, and Trevor were reported very satisfactory and regular in the same respect.

Anatomical Class.—In attendance 72 students, of which number Messrs. Brierley, Harris, Perry, and Roland were reported *very regular;* 39 regular, 13 moderate, 11 indifferent, æger 1, dismissed 3, suspended 1.

Surgical Class.—In attendance 57 students, of which number Messrs. Adams, Brierley, Oakes, Perry and Russell, were reported *very regular;* 34 regular, 11 irregular, 2 very regular, 1 æger, 3 dismissed, 1 suspended.

Practice of Physic Class.—In attendance 42 students, of which number Messrs. Beales, Cantrill, Day, John Fox, Franks, James, Perry, Wilkinson, and Stabb were reported *very regular;* 7 regular, 6 moderate, 16 indifferent, 1 suspended, 3 dismissed.

Midwifery Class.—In attendance 67 students, of which number Messrs. Adams, Baxter, Blake, Bussigny, Berryman, Brierley, Cantrill, Day, Franks, Oakes, Harris, Michell, Perry, Smith, Stillman, Scholefield, Salter, Thornhill, Turner, and Waller were reported *very regular:* 24 regular, 14 moderate, 5 indifferent, 3 dismissed, 1 suspended.

Chemical Class.—In attendance 27 students, of which number Messrs. Brierley, Green, Oakes, Harris, Baxter, and Salter were reported *very regular;* 10 regular, 6 moderate, 4 indifferent, 1 absent.

Anatomical Demonstration.—In attendance 73 students, of which number Messrs. Brierley, Franks, Oakes, Perry, M. B. Smith, Webb, and Wilkinson, were reported *very reyular:* 25 regular, 13 moderate, 24 indifferent, 2 dismissed, 1 suspended.

The Medical Tutor's Class.—In attendance 12 students, of which number Messrs. Franks, Wilkinson, Wall, and Vincent were reported *very regular;* 6 regular, 2 occasional.

The Warneford Theological Class.—In attendance 43 students, of which number Messrs. Brierley, White, and Bussigny were reported *very regular;* 8 regular, 7 moderate, 10 indifferent, 6 irregular, 6 very irregular, 2 dismissed, 1 suspended.

MEDICAL EDUCATION.

The Court of Examiners of the Society of Apothecaries have resolved,—

1. That a preliminary examination for the junior students of the medical profession would be desirable, as an important auxiliary to the subsequent professional studies.

2. That such examination should comprise an inquiry into the student's knowledge of the Latin and Greek languages, and of the elements of mathematics.

3. That students should be admissible to such examination at any period from the date of their apprenticeship to the completion of the first winter session of their curriculum.

4. That such examination should in the first instance include the following subjects, viz.:—

   1. The first book of Virgil's Æneid and Cicero's Oration for Milo.
   2. The Greek Testament, to the end of the Acts of the Apostles; or, the first book of Xenophon's Anabasis,—at the option of the candidate.
   3. Algebra, as far as simple equations.
   4. The first book of Euclid's Elements.

5. That students who pass this examination satisfactorily should not be subject to any subsequent examination in Latin, except the Pharmacopœia Londinensis and prescriptions.

6. That students who have not passed this examination should, for the present, be allowed, as heretofore, to undergo the preliminary examination in Celsus and Gregory, after they have completed two winter sessions of their medical studies.

EPIDEMIOLOGICAL SOCIETY.

At a meeting of the Society, held on the 7th, the following gentlemen were elected to the various offices:

President.—Benjamin Guy Babington, M.D., F.R.S.

Vice-Presidents.—Thomas Addison, M.D.; Richard Bright, M.D., F.R.S.; Sir B. C. Brodie, Bart, F.R.S.; Sir W. Burnett, Knt., K.C.B., K.C.H., F.R.S.; Sir C. M. Clarke, Bart., M.D., F.R.S.; Rev. Thomas Dale, M.A., Canon Res. of St. Paul's; R. D. Grainger, Esq., F.R.S.; Sir Charles Hastings, M.D., Worcester; Sir James M'Grigor, Bart., K.C.B., K.C.T.S.; John Nussey, Esq.; Professor Owen, V.P.R.S.; John Propert, Esq.; G. L. Roupell, M.D., F.R.S.; Thos. Southwood Smith, M.D.; Colonel Sykes, V.P.R.S.; Thomas Watson, M.D.

Treasurer.—T. Addison, M.D.

Honorary Secretaries.—J. O. M'William, M.D., P.R.S.; and J. H. Tucker, Esq.

Members of Council.—G. H. Barlow, M.D.; Jacob Bell, Esq., M.P.; James Bird, M.D.; A. Bryson, M.D., *R.N.*; W. B. Carpenter, M.D., F.R.S.; R. Greenhalgh, Esq.; W. W. Gull, M.D.; A. H. Hassall, Esq., M.B.; E. Headland, Esq.; A. Helsham, M.D.; T. Hunt, Esq.; J. O. M'William, M.D., *R.N.*, F.R.S.; J. F. Marson, Esq., Henry Oldham, M.D.; W. Percivall, Esq.; G. Pilcher, Esq.; E. C. Seaton, M.D.; F. Sibson, M.D., F.R.S.; E. Sieveking, M.D.; J. Simon, Esq., F.R.S.; J. Snow, M.D.; G. J. Squibb, Esq.; Wm. Edwd. Swaine, M.D.; C. R. Walsh, Esq.

HUNTERIAN MUSEUM.

The Council of the Royal College of Surgeons, with a liberality that does them great credit, have sent letters to all the foreign ambassadors and consuls-general, enclosing cards of admission to the museum, which they are invited to present to their respective countrymen who may visit London at the approaching Exhibition of the Industry of All Nations.

COLLEGE STUDENTSHIPS.

The Council of the Royal College of Surgeons have just announced their intention to elect a Student in Human and Comparative Anatomy, at a salary of £100 per annum, to be held for two years, at the expiration of which time the student will receive an appointment in the Army, Navy, or East India Company's Service.

A GOOD HIT AT HOMŒOPATHY.

Professor J. K. Mitchell, in his late Introductory, disposes of Homœopathy thus wittily and aptly:—A Physician educated in Philadelphia, says the Doctor, but who lapsed through a proclivous nature into Homœopathy, came to me once for a motto for a book which he was preparing on Homœopathy. As he usually consulted me when himself sick, and yet gave his microscopic doses to others, I felt no reluctance to give him a blow; so I said that once when a ranting lover on the stage cried out to his mistress—"My wound is great because 'tis small"—the witty Duke of Buckingham added from a side box—"Then 't had been greater were it none at all." Now, Doctor, said I, you can put that together thus—

> "My Physic's great because 'tis small,
> And would be greater were it none at all."

That is the whole argument of Homœopathy in a couplet.

A CHINESE EXECUTION.

A Mr. Lynton has lately made a communication to the Asiatic Society of London, descriptive of a mode of punishment peculiar to the criminal code of the Celestial Empire. A Chinese merchant named Hiam-ly, accused and convicted of having killed his wife, was sentenced to die by the total deprivation of sleep. The execution took place at Amoy, in the month of June last. The condemned was placed in prison under the *surveillance* of three guardians, who relieved each other every alternate hour, and who prevented him from taking any sleep, night or day. He lived thus for nineteen days, without having slept for a single minute. At the commencement of the eighth day, his sufferings were so cruel that he begged, as a great favor, that they would kill him by strangulation.

ROYAL COLLEGE OF PHYSICIANS.

The following gentlemen were admitted members on Monday, the 14th inst.:—Dr. Hall Davis, 17, Russell Place, Fitzroy Square; Dr. Meryon, 14, Clarges Street.

ROYAL COLLEGE OF SURGEONS.

The following gentlemen were admitted members on Friday, the 11th inst.:—Benjamin Baker, Broadway, Worcestershire; John James Bird, Market-Rasen, Lincolnshire; John Hall Bywater, Knottingley, Yorkshire; Frederick Hezekiah Hartshorne, Broseley, Salop; Edward Abraham Hancock Head, Stoke, Plymouth; James Rouse, Walham Green; William Johnson Rowland, Wargrave, Berkshire; Thomas Spencer, East Shilton, Leicestershire; John Hender Tickell, East Looe, Cornwall; Edmond Umphelby, Belstead, Suffolk.

THE FELLOWSHIP.—The following members, having undergone the necessary examinations, were admitted to the Fellowship:—William Adams, New Broad Street; James Alexander, London; Walter R. Howell Barker, Wantage; James Henry Butler, Bengal Army; James Cuthbert Ottaway, Dover.

SOCIETY OF APOTHECARIES.

The following gentlemen passed their examinations on Thursday, the 10th inst.:—John Davies, London; James Hartley, Bury, Lancashire; Charles Matthias Meller, Ecclesfield, York; Watkin Rhys, Aberdare, Glamorgan; John James Ritchie, Tean, Staffordshire; Walter Smith, Caistor, Lincolnshire; Walter Kerr Waller, Lymington, Hants; John Wills, Shaftesbury, Dorset.

The following gentlemen also passed their examinations on Thursday, April 17th:—James Backhouse Bindloss, Manchester; Edward Evans, Cardiff; Edwd. Higgon Evans. Treffgame Hall, Haverfordwest; John Hebden, Scarborough; George May, Reading; Lewis Newnham, Uckfield, Surrey; Hugh Norris, South Petherton; William Johnson Rowlands; Charles Morton Sidley, Leicester.

APPOINTMENTS.

Mr. Hird has been appointed Lecturer at the Charing Cross Hospital School, in place of Mr. Wharton Jones; and Mr. Edwin Canton has succeeded Mr. Hird in the Chair of Anatomy.

Mr. Henry John Brown, of Wilmington-square, has been appointed surgeon to the Parochial Infirmary of Clerkenwell.

Mr. Thomas Carr Jackson, for some years the house-surgeon, has just been appointed assistant-surgeon to the Royal Free Hospital.

Dr. Hooper has been appointed assistant-physician to the Surrey Dispensary, in the vacancy occasioned by the resignation of Dr. John Birkett.

Dr. Edward Smith has been elected lecturer on botany to the Charing Cross Hospital.

BOOKS RECEIVED FOR REVIEW.

The Prescribers' Pharmacopœia. Fourth Edition. London; J. Churchill, 1851. pp. 132.

Syphilitic Eruptions, with especial reference to the Use of Mercury. By Thos. Hunt, M.R.C.S., &c. London: J. Churchill. Pamphlet, pp. 25. 1851.

Practical Analysis of Seventy Cases of Inflammatory, Functional, and Structural Disease of the Heart. By J. Scott Alison, M.D. London: J. Churchill, 1851. Pamphlet, pp. 31.

The New York Journal of Medicine, March, 1851.

TO CORRESPONDENTS.

Communications have been received from Dr. Tilt, Mr. Brown, Mr. Watts, Mr. Harvey.

INTRODUCTORY LECTURE

ON THE

DISEASES OF CHILDREN.

DELIVERED IN THE

Chatham Street School of Medicine, Manchester,

JANUARY 14, 1851.

BY DR. MEREI,

Fellow of the Hungarian Academy, late Professor of the History of Medicine at the University of Pesth, Clinical Professor of the Diseases of Children, and Director of the Children's Hospital at Pesth; Fellow of the Imperial Society of Medicine at Vienna, etc.

GENTLEMEN,—I feel very happy in addressing on this occasion so respectable an assembly. I must beg, above all, your indulgence in judging of my performance of this task, as there will be considerable imperfection of language in it, and perhaps a very limited scientific accomplishmemt.

I have to deliver a course of lectures on diseases of children in this school, and feel very much honoured by this mark of confidence on the side of the learned teachers attached to this institution, and shall try to answer your flattering expectation as well as I can, with truthful accounts of what I have seen and experienced in the arduous department of children's ailments. Allow me, only in the first instance, to premise some few hints about the history and the present state of this science.

Children's diseases have long been neglected, and it would be but a loss of time, should I quote what Hippocrates, Galen, Oribasius, and Paul of Ægina;—what during the long period of barbarism, Rhazes, Avicenna and other Arabs, and subsequent mediœval Christian authors, contain about children's diseases. Excepting some eruptions on the skin, glandular affections, hydrocephalus, convulsions, and a few other chronic maladies, there is very little mention of this department of medical practice. Even in times near to ours, great physicians, as Boerhaave and Stoll, knew very little about children's diseases. Let us, therefore, pass at once to the present century, and mention before all, some German physicians, the first who wrote valuable systematical works on this subject, as Drs. Jörg, Henke, Wendt, Goelis, and some others of that nation.

But if we compare that stage of science with the present, we cannot fail to witness a progress much more important proceeding from French physicians and children's hospitals, commencing with Billard, about twenty years ago, and successfully prosecuted by Bretonneau, Trousseau, Baudelocque, Blache, and some others. The large systematic work of Drs. Barthez and Rilliet (attached to Parisian children's hospitals) is the most important on this subject in modern times. Besides this there are a great many other treatises on children's diseases, more or less special; among these, one of the most remarkable is that of Dr. Mauthner (founder of one of the Vienna children's hospitals) on the diseases of the brain and spinal marrow of children. Great Britain has afforded also some valuable contributions. I will mention Underwood's treatise, that of Drs. Evanson and Maunsell, Dr. West's (of London) "Lectures on Diseases of Infancy and Childhood," full of valuable information, and lastly, Dr. Churchill's (of the Dublin University) very excellent systematical works on that subject. There are also some publications of mine, the last edited of which, (my "Institutions on Diseases of Children,") exists at present only in the Hungarian language.

The most important advances latterly made in this branch of medicine, are of a trustworthy stamp, being founded upon the close observations of thousands of hospital cases, and on an adequate number of pathological dissections.

As children's hospitals form a new and fruitful epoch in the history of medicine, as it is possible that the philanthropic spirit of this country may also take the same direction, and that after the shortly-expected realization of a children's hospital in London, perhaps some of my present attendants could or might one day co-operate in a similar task, allow me to express my opinion on it.

The number of children's hospitals, limited to only two until 1838, one of which was at Paris, the other at Petersburgh, is since that time rapidly increasing on the Continent. There are now three in Vienna, one in Pesth, one at Prague, one in Berlin, one at Frankfort, and in other towns. We observe, that at first were erected nurseries or asylums for poor children, then come soon after them hospitals as naturally connected with the former. I understand by children's hospitals, only those institutions where children are received into the beds, and where the whole organization and accommodation of the locality and of the attendance, is according to the peculiarities of the nature of infants and children, and of their diseases. The most important point is to take infants from one week old and upwards into the hospital; after the tenth year there is much less reason to keep a patient in a special hospital. But then it is an essential consequence, in the instance of such children as are less than three years old, to take into the hospital along with them their mothers or nurses. This is advantageous both for treatment and scientific progress in this department, and I am sorry to say that in this respect, many of the existing children's hospitals are still very imperfect.

That of Pesth was the first founded on that principle, in 1839, by myself with the assistance of my friends; and the number of mothers and nurses whom we kept in the establishment, reached in 1849, above five hundred, besides thousands of little patients. I have been satisfied that everywhere the foundation of a children's hospital met with a general sympathy. That of Pesth rapidly increasing by manifold supports, got a new building specially erected for that purpose in 1845; the goverment following the line of public opinion made of it a clinic and a professorship united with the University, and in 1847 it was decreed, that every student in medicine, in order to get his diploma for practice, should produce a certificate from the children's clinic,

witnessing his attention to this branch of medical instruction. In this particular, the University of Pesth preceded that of Vienna. The foundation of children's hospitals, I am sure, is one of the necessary results of that spirit of inquiry into the state of society, and of increasing philanthropy—both honourable characteristics of this century.

Could I confide in my language, I would endeavour to bring before you a lively picture of the desolate state of the children of poor people, resulting from wretchedness and ignorance. I had under my care more than 15,000 of poor peoples' children, and certainly as many of wealthier families in my private practice. What a melancholy disproportion of state! Improper clothing and nourishment, damp cold foul air and want of light, little care and plenty of prejudices, cause an appalling mortality among the children of the poor.

The figures of proportional mortality seem to be for Pesth the following:—In the *two first years* of life, about 35 per cent. of poor peoples' children die; and hardly 18 in the same time of those belonging to wealthier classes. This disproportion, serious enough, is still greater in the large towns of France and of England. This disproportion of mortality is quite according to the laws of nature, as a tender infant must die, if the essential conditions of the life and development of this delicate organism are not fulfilled; but certainly this is not the intention of the Creator. Then, if you look at these poor little wretches in their state of malady and neglect, covered with dirt and with all sorts of ugly affections on their skin—infants in age, old men in their wrinkled and collapsed face—an appearance enough to revolt human feelings, you must acknowledge that the actual state of society, so much praised, is still very imperfect.

I suppose I am not misunderstood. I am far from saying that children's hospitals are the general and radical remedy against the melancholy conditions alluded to. There are necessities for the moral and physical state of the lower classes, which belong not to me to speak about. But generations may elapse before pauperism and ignorance may be removed, whilst children's hospitals afford a beneficial palliative for a good length of time. They preserve a great many lives of the most neglected children, that is one fact; then, they have been and are the most fruitful ground for the improvement of medical knowledge in this most extensive and delicate branch of practice. I could add, that pathological anatomy of children, the most valuable source of light in their maladies, cannot be duly practised without children's hospitals. And, lastly, they afford the largest opportunity to diffuse instruction and good principles for the physical education of children among poor mothers and nurses, full of prejudices.

Concerning the progress latterly made in this branch of medicine, there is some of a very positive character about the nature of some important diseases of children, such as meningitis, hydrocephalus, all pulmonary affections, typhus, and some others. Thus a positive progress consists in the improvement of objective symptomatology, or what we call the physical examination of the child. Not only its general complexion, or the state of its single parts and organs, *is* now more closely, and *can* be more successfully examined; but there is scarcely a movement, and not one line, imprinted on, or slighty passing over the sick child's face, which is not carefully considered in its diagnostic signification. Let me adduce as an example, that furrow which we call the *oculo-zygomatic line*, commencing at the internal angle of the eye, and extending towards the upper part of the cheek, almost always connected with a collapsed face. This line, if much expressed in an acute case, and if recent and profuse diarrhœa is not present, signifies nearly constantly an affection of the brain. The cry of children decomposed in its two respiratory acts, which we term the *outcry* and the *backdraught* became also the subject of an exact inquiry, at first by Eusébe de Salles and Billard, afterwards continued by some other physicians. But the most splendid progress in children's diagnosis is realized by the application of auscultation and percussion of the chest in children's practice. A practitioner well informed in this sort of examination, will be able to point out with nearly mathematical certitude the seat, the species, and the degree of any affection of the bronchi, of the lungs, of the heart, and the connected parts. And as in febrile affections of little children, there is frequently much obscurity about the seat of the prevalent local affection, as for example, whether it be the brain or the lungs, it becomes clear, that in becoming enlightened upon the state of the lungs, we are enabled to make a conclusion about the state of the brain, and consequently this kind of examination affords us a basis—a good directory in the diagnosis of at least the half, in number, of acute and febrile affections of children. Therefore I shall insist in particular upon that point, and practise auscultation and percussion on sick children brought to us in the course of my lectures.

In conclusion we can say, that by all these improved means of objective and physical examination, the speechless child by-and-by becomes the book of nature, legible to a certain extent by the well informed practitioner.

I cannot say as much as this in favour of the treatment. There are improvements also in this part, it is true: the progress in pathology and in diagnosis, could not fail to advance the therapeutics. We have also obtained some better information about the action and the method of applying usefully *high doses of iodide of potassium*, in *certain* species of dyscrasy, and not as it has been stated, in general in the large and vague department of scrofula. *Cod-liver oil* is already demonstrable to be the sovereign remedy of all sorts of atrophy or deficient vegetation, and this is an indication important enough, (we must not pretend too much for one remedy); thus I have, myself, succeeded in proving, by hundreds of facts, in the children's hospitals of Pesth, that the ammonio-sulphate of copper, administered in full doses, in an aromatic solution, is the sovereign remedy of all cases of chorea, unconnected with organic alterations of the nervous centres. Dr. Trosseau, of

Paris, has improved the treatment of laryngeal croup with the ingenious application of an operative act. I could mention some more facts as proofs of a progress in children's therapeutices. But this progress is neither sufficiently considerable nor general enough.

The rudest empyricism, and strange and unnatural systems of treatment, can still subsist along with the general line of practice. This fact makes it clear that there must be still a good deal of superficiality and imperfection in our therapeutics.

It seems to me that the curative power of nature is not yet valued as it ought to be, and this is in itself a continuous source of uncertainty, of mistakes, and of improper remedies.

Hippocrates, the genial physician of an enlightened people, said:—"Medicus naturæ minister sit, neque tyrannus,"—that is to say, we are but the servants of nature. But the light of Greece was extinguished, and then the mediœval darkness came over us, and with it the blind faith in remedies; and professional men became the tyrants of nature indeed, overloading the sick with physic, as if there was never a chance of getting well without it.

This tremendous polypharmacy, the most mischievous in children's practice, lasted for more than a thousand years. Latterly it has been very much reduced, and the most enlightened practitioners are at present the most simple in their treatment. But this is not enough.

If, then, somebody tells us that a child, unsuccessfully treated with our medicines, was restored to health by a system quite different from ours, it is not enough to demonstrate it physically or chemically that such and such a treatment could not exert the least influence upon the body, nor to state that in such cases nature performed the cure. All this is not enough.

The *reform* we need must have two essential consequences: *simplification and negativeness* on the one side, and *improvement of active treatment* on the other side. It must be shown what nature *can*, and must be *allowed* to do, and what a remedy can, and in what cases and circumstances it *must* do.

It is quite insufficient to say, as we do frequently, I have seen many and many patients get well under such or such a treatment, as nature and hygienic circumstances are powerful enough to cure suddenly or slowly the greatest number of sick; thus to antimonials is attributed an antiscrofulous action, to mercury a remedial virtue against the inflammations of the brain, and so forth. The important fact is, that *there is no one malady, which we can cure with remedies, which is not cured very frequently by nature alone;* the therapeutic question is consequently only a relative one to the proportional number and length of time of our cures, therefore we must seek to construct a sort of comparative experimental system, comparative between the natural course of diseases, and that influenced by active remedies. This is a task for hospital practice, which, however imperfectly commenced to-day, will sooner or later be generally adopted. I understand here *well-organized* hospitals, completely provided with a good medical attendance, of which there are already a great many in Europe. Under such a careful attendance can be established certain *conditions* under which a disease, acute or chronic, may be abandoned to its natural course; and other conditions, under which, and in what manner, we must interfere with active remedies, in both cases exactly watching over and describing the course of the maladies. In this way by-and-by we shall be in possession of thousands, and hundreds of thousands, of exact histories of this double kind, and shall be enabled to appreciate with more certitude remedies and methods of treatment. I am sure that all the learned members of this school, and all enlightened practitioners agree with me, that medicine will *stand this trial*, and that the result of this enlightening of ourselves as well as the public, upon the curative power of nature, will be in favour of good practitioners, and only unfavourable to ignorance and charlatanism.

The position of our profession is something more than that of *only* prescribing remedies. For my part, as I have been utterly convinced that the principles just now mentioned are the most important for children's practice, I applied the comparative experimentation in the children's hospital since 1842, consequently there is only mention about the results in my last-edited work. At present I have not at my command statistical figures concerning that point, but I can say we have been satisfied that there are diseases of children, or circumstances at certain times in the course of a disease, where remedies are good for nothing, or they are mischievous; but there are other diseases or other circumstances under which a judicious treatment promotes and insures a complete cure; then, lastly, there is a small per centage, (taking all diseases together,) where only by a suitable active treatment death can be prevented.

Syrups, emulsions, and similar things, are not indifferent: they are mischievous to the tender stomach of a nursling, and ought to be very much reduced. Our books contain hundreds of comparative facts, showing that *mercury* is at least useless in the advanced stage of hydrocephalus, indifferent, or just acting as a purgative in meningitis, and that besides its purging action, that on the liver and its specific antisyphilitic quality, nothing appears to be clear about other actions attributed to this flexible sort of panacea, if administered in small or moderate doses; and, what is the most important, we have at command a great number of cases illustrative of the unfavourable influence of calomel upon the digestive organs, the blood, and the bones of children. The strong mercurial ointment, carried to the effect of mercurial fever and crisis, produces sometimes deep changes in the fluids and solids, sometimes beneficial.

We have at command comparative facts concerning *hooping-cough*, showing that pure nervous cases, abandoned to hygienic means, to open air, (always excepted cold damp weather,) are more favourably restored to health than those that are treated with all the recommended active remedies, and confined to the room. I repeat it, I am speaking of *pure* convulsive hooping-cough, as, if there be a complication of bronchitis, or of something else of importance, then we may very usefully interfere with on occasional active treatment.

We have seen epidemics of this affection where many cases required some months till they recovered, whilst in some other epidemics, cases occurred getting well by nature alone in one or two weeks. Thence the mistake in estimating remedies. It seems to me that, if we were to find out the true specific for this nervous, and frequently even periodical affection, its action will be, perhaps, as quickly curative as that of quinine in intermittents. We have found that the most favourable results as regards recovery, and the time of it, was on the side of the hygienic, or at least very simple treatment—of all *simple* fevers, not complicated with inflammation or other important derangement, including even typhus. With water, (cold and warm,) oil, fomentations, poultices, and injections, can be very well treated many severe fevers of children.

I think that these results, however negative, are worthy to be brought under the notice of pupils and young practitioners. It is very preferable in every description of practice, but above all in children's practice, to abandon a case to nature, assisted by the most simple means, rather than to attack the constitution with a mass of medicines without full knowledge of the case, and of the effect of its medicines. The time must come when, in the hospitals and clinics, pupils and new practitioners will be accustomed to see sometimes a severe disease running through its course without interference; this time is not yet come, but will come, and will contribute to develop a certain firmness of character in practice.

But now I must mention also some positive results. I pass over in silence the quantity of cases and circumstances where an occasional active interference insures the completeness of recovery, and mention, before all, intermittent fevers. I dare to say that autocracy of nature cures 10 per cent., but active treatment at least 90 per cent., of them shortly and favourably. Thus out of 100 cases of acute lobar pneumonia in *little* children abandoned to nature, I am sure about 90 per cent. will die; and active treatment applied in the *first stage* of hepatization, will have in its favour about 30 recoveries. And if Dr. Dieth, of Vienna, or some other, speaks unfavourably about the results of bleeding, this is owing to the advanced and neglected state of pneumonia, with which, in general, adult patients enter the hospitals. Active treatment is very favourable also in capillary bronchitis, as well as in almost all acute parenchymatous and serous inflammations.

Our result concerning chorea I mentioned already. This disease abandoned to nature runs from six months to two or even more years, whilst our above-mentioned active treatment had, in 147 cases, 140 speedy and complete recoveries. Dr. Trousseau, of Paris, has recently adopted it, at my recommendation, in the hospitals of that city. But I shall not persist any longer in detailing similar observations. Our results are very little in comparison to what can be expected by the farther progress in a well-managed hospital experimentation.

The physical education of infants and children is also an important point, advancing parallel with this branch of science, but it is too late in this instance to enter into particularities. I am sorry to say that the microscopical examination of the milk of the breast, commenced by Dr. Douné, and even the chemical examination, are not yet arrived at the desirable height of practical importance. In conclusion, this branch of science has already reached to a degree of development and usefulness, worthy the attention of the profession.

I shall at the next lecture enter into detail and specialities.

OBSERVATIONS ON THE CÆSAREAN SECTION,

By G. B. KNOWLES, Esq., F.R.C.S., F.L.S., &c.,

Professor of Botany and Materia Medica, in Queen's College, and Surgeon to Queen's Hospital, Birmingham.

ATTEMPTS having been lately made to throw a degree of odium upon the Cæsarean section, and the most unwarrantable epithets having been applied to that operation, I am induced to offer, through the *Provincial Journal*, a few remarks upon this interesting and important subject.

In the discussions upon the Cæsarean section at the meetings of the Royal Medical and Chirurgical Society, in February last, allusion was made by Dr. Robert Lee to my successful case of Cæsarean operation. The case was published in the 4th vol. of the "Transactions of the Provincial Medical and Surgical Association;" but as some years have now elapsed since the publication of the case, it may not, perhaps, be uninteresting to some members of the Association to be made acquainted with a few particulars respecting it.

The operation was performed in May, 1835; and in the autumn of the same year brief notes of the case were read in the medical section at the meeting of the British Association, in Dublin. By some unaccountable mistake it was subsequently announced that the operation had been performed by Mr. Knowles, *of Manchester;* and it was so reported in the various periodicals of the day. The same error has been repeated, even a few months ago, in the *Edinburgh Journal of Medical Science*, and also in the new edition of Dr. Churchill's midwifery. I have thought it right, therefore, that the error should be corrected; and I am induced more especially to bring the case again before the notice of the profession, in consequence of a remark made by Dr. Lee in his address at one of the meetings already mentioned. Dr. Lee, after excluding (and apparently with great propriety) the case of Mary Dunally, and that of Mrs. Barlow, proceeds to state that "Mr. Knowles' case, and that of Mr. Cluley, related by Dr. Radford, are the only two real cases of recovery out of fifty performed in Great Britain and Ireland; *and whether these persons are now alive, and in what condition they are, no one can tell.*" I give, therefore, a brief account of the case.

Sarah Bate had long been the subject of *mollities ossium.* She had had four labours and four miscarriages in about eight years; and it was during the space of time in which these miscarriages took place,

that the disease in her osseous system commenced, as she became very lame and complained of constant pain, which she believed to be rheumatism. In her last or ninth pregnancy, *I did not see her till labour had commenced*, at the full period of utero-gestation. After a most careful examination, in which I was assisted by my friends Mr. Wood, senior-surgeon to the General Hospital, Mr. Wickenden, and the late Dr. Ingleby, it was ascertained that the space left by the distorted bones, was only two inches in the transverse, by less than one in the antero-posterior diameter. The sacrum and lower lumbar vertebræ had, in fact, so far descended into the cavity of the pelvis, as to occupy the greater portion of its space. This will readily be imagined when it is stated that, after her recovery, she was found to have diminished in stature full *nine inches*. In such a case there could be no question as to the mode of practice to be adopted; and even Dr. Lee, I should think, must admit that in such a degree of deformity the Cæsarean section was the only alternative.

Of the propriety of inducing premature labour in certain cases of deformity, there cannot be a doubt in the mind of any man who has had much experience in the practice of midwifery. When a student, more than thirty years ago, I have heard Sir Charles Clarke in his lectures dwell with great earnestness upon its important advantages, and in the course of my practice I have frequently availed myself of his valuable suggestions with the happiest results. But at the full period of utero-gestation, the choice will sometimes lie between craniotomy and gastro-hysterotomy. Now, to decide upon the possibility of delivery by craniotomy in cases of extreme deformity, is, doubtless, a point of no small difficulty; for, in using the perforator and the crotchet, it has long ago been observed that *it is one thing to extract, and another to extract with safety*. My experience, in fact, leads me to believe that craniotomy has often been attempted, and perhaps effected, when the Cæsarean section might have offered the patient an equally good, nay, perhaps a better prospect of recovery; for I am of opinion, that if all cases of craniotomy were recorded that have terminated unfortunately, they would form a most fearful and appalling catalogue. Baudelocque, indeed, does not hesitate to assert, that if practitioners had recorded all those cases in which they have delivered, or attempted to deliver, by the use of the crotchet, as has been done with regard to those who have undergone the Cæsarean section, it would not be difficult to prove that many more women have died from the use of the crotchet, than from the Cæsarean operation. In cases of extreme deformity it most frequently happens that the practitioner has no knowledge of the state of the pelvis until labour has actually commenced; an estimate must be made, therefore, between the comparative danger of craniotomy and the Cæsarean section.

It must be freely admitted, and should be regarded indeed as a general rule, that where there is sufficient space to admit of delivery by the crotchet, and with a reasonable prospect of safety to the mother, we should never hesitate to have recourse to this mode of practice in preference to the Cæsarean section. Now, that every experienced and well-informed practitioner would invariably keep in view and act upon this rule, I cannot for a moment entertain a doubt; inasmuch as the life of the mother will always be considered as more valuable than that of the child.

I cannot but wonder, therefore, that Dr. Lee, in his reprobation of the Cæsarean section, should have so far forgotten himself and the courtesy that is due to the profession, as to have made, in the course of his speech already alluded to, the following unwarrantable remarks:—"This rage," says Dr. Lee, "*for cruel and bloody operations*, has spread far and wide, and *attempts are being made on all sides in this country, at the present moment, to pervert and corrupt the sound and fundamental doctrines of English midwifery*; as a public teacher, and holding a public position, my *conscience* will not permit me to remain a silent witness of *such abominations*." Can this accusation be, for a moment, considered justifiable? Have not accoucheurs in general the same anxious consideration for the welfare of their patients as Dr. Lee? Would they be at all likely to be influenced in their judgment by the *eclât* attached to an operation? Would any one, in short, venture upon the hazardous operation of gastro-hysterotomy, except under circumstances in which it seems to afford the only practicable means of delivery? Certainly not. Where, then, are we to look for *this rage for cruel and bloody operations?* Where are *attempts being made to pervert and corrupt the sound and fundamental doctrines of English midwifery?* Nowhere, I verily believe, except in the prejudiced and angry mind of Dr. Lee. Nor am I disposed to admit, that Dr. Lee's *conscience* is more sensitive upon these points than are the consciences of those against whom he has directed his attack. It should be remembered, moreover, that no comparison can be drawn between ovariotomy and gastro-hysterotomy; the necessity for the former being but rarely very urgent, the latter never admitting of delay.

And what, after all, are the circumstances that seem to have called forth the severe animadversions in which Dr. Lee has indulged? It appears that the Cæsarean section has been performed lately in two or three cases in which, according to Dr. Lee, the operation was unnecessary. In Mr. Skey's case, for instance, Dr. Lee maintains that he could have effected delivery with the perforator and crotchet, although the diameter from the base of the sacrum to the symphysis pubis was only one inch and one-eighth. I have no doubt of the adroitness of Dr. Lee in the use of these instruments, yet I much question the possibility of effecting delivery by cephalotomy in such a case with safety to the patient; and such appears to have been the opinion of the distinguished practitioners who met Mr. Skey in consultation. It seems that neither Dr. Lee, Dr. Collins, nor Dr. Joseph Clarke, have ever met with a case in which the Cæsarean section was necessary. This is very remarkable, and yet very possible, even in the very extensive practice in which these gentlemen have long been engaged. That cases do sometimes occur, however, in which delivery, *per vias naturales*, is utterly

impracticable, and in which the Cæsarean section offers the only possible means of relief, is a fact that cannot be denied. "The necessity for this operation," says Baudelocque, "is no longer a problem; it cannot now appear doubtful to any persons, except to those who are interested in opposing it, whatever may be the motive by which they are actuated. Its necessity is as fully established as that of lithotomy, to which no one will dare to object, because it is, in some instances, as impossible to extract a child through the natural passage, as to bring from the bladder a large stone through the urethra. The Cæsarean operation has this peculiarity, that it is always urgent, whilst lithotomy is scarcely ever so; that the least delay in the former may render it useless to the child, and more dangerous to the mother, whilst the latter may, perhaps, be deferred without any material inconvenience."

It is more than probable that recourse has been had to the Cæsarean section, when the patient might possibly have been delivered by cephalotomy; but has no limb ever been removed by amputation, which might have been saved by other treatment?

In the case of deformity at Cupar, in which Dr. Simpson was consulted, and in which it was decided that the Cæsarean section would be necessary, the patient was very unexpectedly delivered, and even without instrumental assistance. When we are made acquainted, however, with the state of the fœtus, we cease to wonder at this unexpected delivery; for it appears that "the infant had been dead for some time *in utero*;"—that the bones of the crainum were separated from their attachments, and floated about in the dissolved and liquefied cerebral matter;—that, although eighteen inches in length, it weighed only three pounds and three ounces;—that, in fact, it was in a state of putrefaction.

Dr. Lee exults in this unexpected termination of the case, and so must every one who possesses the common feelings of humanity; but has it not frequently happened, that a case of hernia, after resisting all attempts to return it, has receded spontaneously while the surgeons were deliberating upon the probable necessity for an operation?

But Dr. Lee does not seem to be aware of the fact, (or else he withholds it,) that the Cæsarean operation has been much more successful on the Continent than in this kingdom. The statistics in this matter are, in all probability, not strictly correct; and yet if allowance be made for various fatal cases not recorded, we shall find, even then, a considerable number of well-authenticated cases, amply sufficient to prove that recovery after this operation is by no means so hopeless as Dr. Lee would wish to make it appear. M. Simon, in his "Recherches sur l'Operation Cæsarienne," has investigated the subject with great labour and accuracy, has proved the possibility of operating with success on the living mother, and pointed out the peculiar circumstances under which it ought to be performed. The successful cases enumerated by him amount to seventy-three, among which are four instances in which the same woman had undergone the operation *twice*; two *three times*, one *five times*, one *six times*, and one *seven times*. The successful cases enumerated by Baudelocque as having occurred since 1750, amount to *one hundred and thirty-nine*, the unsuccessful ones to *ninety-two*. There is no doubt, however, that this statement, as regards the number of unsuccessful cases, is incorrect. But among modern practitioners no one seems to have performed this operation so frequently, and with such extraordinary success, as Dr. Hæbeke, of Brussels, who is stated to have performed it thirteen times, and thus to have succeeded in saving *ten mothers* and *nine children*.

A few years ago I was favoured by Professor Gibson, of Philadelphia, with notes of his two interesting cases of Cæsarean operation, which were performed by that distinguished surgeon upon the same woman, and were both equally successful. The first was in March, 1835; the second in November, 1837. It appears, according to Dr. Gibson's account, that these were her third and fourth labours, and that in her two previous labours she had been delivered with great difficulty, after the destruction of the child by cephalotomy. Here again the Cæsarean section was not decided upon until it was ascertained that delivery by cephalotomy could not be effected with safety to the patient. I do maintain, therefore, (notwithstanding Dr. Lee's condemnation of the Cæsarean operation,) that where the deformity is such as to make it scarcely possible for cephalotomy to be performed with safety to the mother, we are bound to take into consideration the safety of the child, and are perfectly justified in having recourse to the Cæsarean section.

This is the only point of view in which we should regard the Cæsarean operation, namely, as a *dernier resort* in cases where delivery by the ordinary means appears to be impracticable.

The question at issue has been ably and carefully considered by Dr. Radford, of Manchester; and the relative value of craniotomy and the Cæsarean section has been justly and impartially estimated by that gentleman in a paper published in the *Provincial Medical and Surgical Journal* of April 2, 1851. The sound and practical view taken by Dr. Radford of this important subject, should entitle it to a careful and serious perusal by every obstetric practitioner.

It is unnecessary, however, to carry the argument further; and I will merely add, for the information of those who may feel an interest in the subject, that my Cæsarean patient, Sarah Bates, *lived five years after the operation*, when she died of pulmonary consumption, her husband having died about twelve months previously of the same disease. The child *lived ten months*, when it was suddenly taken off by a fit of convulsion caused by dentition.

NOVEL OPERATION

FOR

EFFECTING RE-UNION OF UNUNITED TENDO-ACHILLIS.

By Dr. LITTLE,

PHYSICIAN TO THE LONDON HOSPITAL, AND FOUNDER OF THE ROYAL ORTHOPÆDIC HOSPITAL, ETC.

It is the duty of every practitioner, from time to time, to review his experience in treatment of disease for the purpose of offering to the consideration of his medical brethren any facts that may appear to be either in themselves interesting, or suggestive of further applications of the principles of our art. I adduce this truism of our profession as an excuse for publication of a case which happened several years ago.

In 1841 I was consulted by Mr. Jackson, of Spitalfields, concerning the lameness of a young lady, of fair temperament, and somewhat delicate, aged 11 years, who, four years previously, after "influenza," was attacked with inflammation of the right knee, succeeded by suppuration and consequent contraction of the knee and ankle. Several cicatrices, not extending more deeply than the integuments, were visible on front of the knee and posterior part of the leg. The knee was only slightly contracted, but the ankle presented the form of complete talipes equinus, the heel having been elevated to the utmost extent. The cicatrices having been superficial, indicated that the suppuration had not involved the bones, ligaments, or any parts beneath the deep fasciæ of the limb, (usually an important indication, since it shews probable facility of removal of deformity.)

The tissues on the posterior aspect of the leg, and especially the tendo-Achillis, were proportionally shortened; attempted elongation of these parts, and consequent flexion of the ankle-joint, were effectually resisted. The limb was slightly shortened, less fleshy, and the foot smaller than the corresponding parts of the left side. The act of walking was accomplished with the efforts usually required in talipes equinus, the metatarso-phalangeal articulations only, bearing the weight of the frame.

The case was justly regarded as one of contraction of the posterior structures of the leg—the superficial and deep muscles with their tendons, the fasciæ and posterior ligaments of the knee and ankle-joints—which had resulted in the first instance from the flexed position of the knee and extended position of the ankle-joint, required for relief from pain during the inflammation and suppuration of the limb. It was further concluded, that as after subsidence of the inflammation, and healing of the suppurative wounds, attempts to restore the flexibility of the affected articulations had been postponed lest extension should re-excite inflammation, the parts had become so fixed in their contracted position, that the aid of tenotomy would be indispensable for restoration. The limb had been thus contracted only four years, but experience had previously taught me that a comparatively greater amount of shortening of a muscle will take place during four years in a growing child, than in an adult. It has been stated that other parts, besides the gastrocnemii, were shortened; it was, however, determined to sever only the tendo-Achillis and peronei, because, as it is now well known, in all cases of contracture of the ankle, whether from paralysis, spasm, or inflammation, the gastrocnemii offer a preponderating resistance. The greater resistance of gastrocnemii than of other structures, arises from the peculiar arrangement of that muscle, the tendon of which, owing to its attachment to the posterior extremity of the os calcis, is far removed from the axis of the ankle-joint, and greatly differs in this respect from the tendons of the remaining muscles of the posterior aspect of the leg, which lie almost immediately in contact with the ankle-joint.

The consequence of the greater distance of the tendo-Achillis from the axis of motion is, that a greater amount of lengthening of that tendon than of the deeper parts is necessary for restoration.

It was determined to include peronei in the operation, as these muscles had often been found to resist replacement in cases of complete talipes equinus.

The slightly contracted state of the knee, although in the first instance the result of the inflammation about that joint, was also maintained by the shortening of the gastrocnemius; for this muscle, being attached above to the femur and below to the os calcis, passes over both the knee and ankle-joints; and, consequently, when contracted to the utmost, limits the movement of both articulations.

Oct. 1, 1841.—Section of tendo-Achillis and peronei by the subcutaneous mode of proceeding. The foot was lightly bandaged on a straight splint in the contracted position. A day or two later the observation was made that a due quantity of adhesive medium around the severed part of the tendo-Achillis had not been poured out, which was attributed to coldness of the weather and weakness of blood-circulation in the member. The foot and leg were therefore enveloped in cotton wadding, and replacement of the foot in the natural position postponed until better evidence of union of the tendon appeared. A few days afterwards, re-union appearing to have advanced, the extension apparatus was applied, and the foot too rapidly flexed to the utmost. In short, it was noticed that no tangible resistance was offered to restoration of the natural form and flexibility.

At the expiration of a month she was permitted to walk. She was enabled to do this most easily, as the sole was evenly applied to the ground, the foot could be fully bent, and the knee, which had been well rubbed and manually extended, was perfectly straight. She availed herself too readily of the permission to walk; for her parents, seeing the improvement in position and the child's recovered activity, could never be persuaded to treat the case as of sufficient gravity to require care in not too rudely treating the severed tendons. I entertained doubts whether the tendo-Achillis had united. At the end of the sixth week it was evident that the fears of imperfect union which had been entertained

within the first week of the operation were fully justified. The state of matters was as follows:—The child appeared to an ordinary observer to walk as well as patients usually do at the expiration of six weeks after division of the tendo-Achillis, that is to say, with stiffness and awkwardness rather than with lameness. I perceived, however, that the child trod exclusively on the heel; that the anterior and some of the external muscles of the leg were inordinately active, and inclined to raise the front of the foot, and to evert it. No doubt could exist that the muscles of the calf (and the more deeply seated muscles of the leg) offered insufficient resistance to the anterior muscles. The state of the tendo-Achillis was most unsatisfactory: the divided extremities were seen and felt nearly two inches asunder, still somewhat swollen; they appeared to be connected by a thin strip of ligamentous or other band, probably only the thickened fascia. The ankle-joint was particularly loose—too flexible—the result of want of support and tension behind from the tendo-Achillis. On examining the sole, I noticed that the cushion of the heel, previously small from disease, was already becoming disproportionately large, whilst the metatarsal part of the sole bore no appearance of use. It was evident that the child had been allowed to walk much more and earlier than Mr. Jackson and I had sanctioned, and that the foot was rapidly acquiring the shape of the deformity which I have named talipes calcaneo-valgus.* This deformity, if unchecked with advancing age, is even a greater evil than talipes equinus; hence our patient had made an unfortunate exchange. The parents' hopes, professional reputation, not less than the credit of the operation of section of tendo-Achillis, then only recently introduced, demanded an effort for recovery of the patient's limb. Having originally regarded the case as one peculiarly favourable for the operation of tenotomy, in consequence of its simple origin and the absence of paralysis or spasm of any muscles, I was the more disappointed at the impending permanent great lameness of the child. I therefore, after trying a few days' replacement of the foot in a distorted position, without any appearance of tendency to re-union, proposed to Mr. Jackson an operation for effecting union of the tendo-Achillis.

Nov. 20.—Performed the contemplated operation for effecting re-union of tendo-Achillis. The patient was placed in the prone position. Holding an ordinary narrow sharp-pointed tenotomy knife† in a position transverse to the limb, I introduced it through the integuments on the outer side of the ordinary course of the tendo-Achillis, near the spot where the section of the tendon had at the outset been effected. After traversing the integuments, I shifted the direction of the tenotome, directing it parallel to the limb, carrying the point of the knife upwards towards the superior end of the tendo-Achillis, and with it lacerating any adhesions the tendon might have contracted in that situation, as well as the face of the severed end, so as to ensure exudation of blood and plastic matters from its surface; the point was then swept downwards, along the interval left by the retracted upper end of the tendon, towards the cut surface of the lower portion of the tendon; this was similarly lacerated, and the knife withdrawn. A puncture in the integuments remained, through which a few drops of blood issued. The previous gap between the ends of the tendons was now occupied by a considerable sanguineous effusion.

The steps of this operation, which I have thus fully detailed, occupied but a few seconds, and caused but trifling pain, compared with the important probable result of re-union of the tendo-Achillis. The knee, leg, and foot, were now carefully but not tightly bandaged in the extended position, so as to approximate as nearly as possible the severed ends of the tendon, and to keep the knee and ankle joints in repose. Neither inflammation nor pain followed. At the expiration of a fortnight the splint and bandage were removed. Abundant effusion of plastic material and adhesion of tendon had taken place. Very cautious bending of the ankle was now effected. In ten days it was reported that the foot was flexed to an angle of 45°. At the expiration of a month permission was given to recommence gentle exercise, using a laced boot supported by an iron stem. At the end of the sixth week the report states:—"Union of tendo-achillis perfect, the foot is perfectly flexed, the knee straight and flexible, she walks in a common boot, and is this day discharged cured."

I occasionally saw this patient afterwards. No trace of talipes equinus or of talipes calcaneo-valgus remains; indeed restoration was complete.

The entry in my journal says:—"Jan. 18, 1845.—The tendo-Achillis somewhat longer than natural, slightly thickened at the operated part; no adhesions to integuments; right surales short; difference between bulk of the muscles of the calf on both sides inconsiderable. Walks perfectly free from lameness."

Remarks.—I am induced to give publicity to this case less as an instance of successful cure with the aid of tenotomy than to point out the manner in which an accidental failure of union of a severed or ruptured tendo-Achillis might be repaired. The instance I have related shows that non-union of a severed or ruptured tendo-Achillis, although a rare occurrence, is not a mere hypothetical case.

I have witnessed several instances of incomplete union of that tendon after section, but as the operation had been resorted to for relief of paralytic or spasmatic contraction, failure of complete re-union did not render an additional plastic operation necessary. I have been consulted, however, by a gentleman, who two or three years previously ruptured a tendo-Achillis on board ship; the accident had been unfavourably treated, the tendon remained ununited, the state of the foot and the mode of walking corresponded with that reported of my patient at the sixth week after section of the tendon.

* *Talipes Calcaneo-Valgus*—A deformity of the foot, in which, either from paralysis of gastrocnemii, or spasm of front muscles, the individual walks exclusively upon the heel, and unduly everts the foot. See lectures in the *Lancet*, 1843-44.

† Represented No. 2, figure 41, "Treatise on Club-foot" &c., by the Author.

He experienced very great inconvenience from the want of the acting tendon of one gastrocnemius and soleus. Indeed the amount of weakness and lameness likely to result from the entire abolition of the functions of the muscles of one calf, in a stout previously active man, can be readily appreciated. These muscles are part of the distinguishing characteristics of bipeds, and man cannot, without much impairment of function of the ankle and foot, dispense with them.

The causes of non-union in the child appeared to be diminished effusion of plastic matter immediately after section of the tendo-Achillis, due to languor of circulation, either the consequence of some inherent vice of constitution, aggravated by the too sudden elongation of the space between the severed ends of the tendon, either by the mechanical instrument used, or by the injudiciously early walking exercise. The slowness with which wounds cicatrize in an arctic climate is well known. I have witnessed a puncture resulting from subcutaneous tenotomy bleed like a fresh puncture ten days after operation, during the rigours of a severe Berlin winter; and frequently in cold weather in our own country I have found it necessary, after tenotomy, to envelop with cotton and flannel a feeble, partially paralyzed limb, in order to accelerate union. The influence of too considerable and too early separation of the ends of a severed tendon, and especially of frequent motion, as in walking, in interfering with union, is incontestable. The reparative powers of the system, however, usually suffice to neutralize any injury from too great or too hasty separation. Experiments upon animals have proved that considerable lengths of tendon may be excised, and union nevertheless ensue; but the knowledge possessed of the great extent of the powers of the economy and of a part, is an insufficient reason for neglect of those rules and acts of caution which experience dictates. The immediate separation of a severed tendon to too great an extent should be avoided. Half, or three-quarters of an inch, may be safely borne, although as a rule gradual separation is preferable. The condition of a severed tendon approaches that of a fractured bone; too great separation of the severed ends, depression of temperature sufficient to suspend active arterial circulation, too early movement of the parts, and inherent vice of constitution, will cause tendon and bone to remain ununited, to the great detriment of the sufferer.

An ununited fracture of a bone is repaired by approximation of the ends, by repose of the limb, by suitable means of maintaining arterial circulation, and by exciting through the help of setons, friction of the extremities against each other, what some surgeons term inflammation, in reality exudation of plastic materials from the blood.*

In my simple operation I adopted an analogous course to procure union of ununited tendon, the prompt action of the point of a knife being substituted for the tardy action of the seton. I may presume to inquire of surgeons, whether the introduction of a fine tenotomy knife between the ununited ends of a bone and the laceration of the sluggish parts, disinclined to exudation of lymph, might not advantageously be tried in lieu of the seton, in the use of which additional delay is occasioned. I am not unaware of the difference between the relative susceptibility of bone and tendon to the action of a cutting instrument. It is probable that at the period when means are required to excite union of a long ununited fracture, the ends of the bone may, in some instances at least, have acquired a greater softness of structure. Several surgeons have demonstrated the value of section of tendons in these cases as a means of obtaining repose of the member.

I do not propose this case for imitation as regards the application of tenotomy for the cure of the contracture. Later experience has taught me that numerous cases operated on ten years since might, probably, have been relieved without operation. The facility with which this case yielded after operation, occasioned the regret that I had not previously caused patient and persevering manipulation and mechanical extension to be tried under my direction. In the present day, I frequently witness unnecessary performance of tenotomy. This, like all other operations involving a solution of continuity of parts, should, in cases offering a probable prospect of cure without operation, be regarded only *en dernier ressort*. Tenotomy should only, as an exception, be placed in contrast with other modes of treating deformities; occasionally, when not indispensable, it may compete with mechanical treatment on the ground that, by its means, time, trouble, pain, and expense are saved. But in many deformities it should be resorted to only when trial of other means has failed. Time and experience alone will enable the practitioner to decide or lay down rules when the operation is indispensable. This time has, in my opinion, arrived. Sub-cutaneous tenotomy has passed triumphantly through the ordeal of a long trial, and is recognized as a great blessing conferred by Stromeyer upon humanity. Let us hope that, unlike all that is good and useful, it may no longer be abused.

Finsbury Square, April 7, 1850.

* This was written before hearing Mr. Stanley describe at the Pathological Society of the Metropolis, the interesting and successful experiments made by Mr. Teale of Leeds, and himself, by driving ivory wedges between the ununited ends of bones. Mr Teale has displayed a happy acumen in taking up the neglected method of Dieffenbach. May not the method operate not less by tending to maintain the severed ends at rest, than by causing exudation of organizable material. After the demonstration afforded by the experiments in question of disintegration of those portions only of the ivory wedges introduced beyond the periosteum, how many new thoughts suggest themselves.

SEXAGENARIAN THOUGHTS

ON THE

PRESENT STATE OF THE MEDICAL PROFESSION.*

You will observe, Mr. Editor, that I do not enter upon the *vexata quæstio* of medical reform; that I give no opinion as to what is best to be done, or to be left undone; but, as unattached to any party, unbiassed

*Concluded from page 241.

by previous prejudice, unfettered by early declarations, as an observer for many years past, I do not hesitate to praise or to *blame* wherever I consider praise or *blame* to be due.

Now let me follow these high-minded individuals into practice, and let me examine whether they are as independent of trading principles as they profess to be. In the first place it must be allowed, that the profession is grievously overstocked, and that, as a natural consequence, its talent when brought into the market, is too lightly estimated, and is very badly remunerated. This is the natural consequence of the too great abundance of any commodity, whether physical or intellectual; and the result is, that men feel disposed to bring their talents to a cheap market rather than to starve. The consequence of this is a very undue *competition*. No sooner is a union advertised as vacant, than there are a host of candidates; as in the case before us, the stipend is fixed, and, therefore, they cannot underbid each other: but the number of eagerly canvassing candidates proves to the Guardians how earnestly their votes are sought for, how thankfully—I might say, how abjectly obtained; and they at *once* infer that this can only be because their stipend remunerates. And whenever any Union medical officer vacates his position for an increase of salary, what is the conduct of the Guardians? Taught by uniform and unerring experience, they advertise for a successor; not one or two, but a host present themselves; one is chosen, and thus a new medical man is introduced to take off another slice from the already scanty loaf of the practitioner. To avoid this increased competition, the stationary practioner submits to the oppressive weight of the law *as it is*. And what is that union with regard to remuneration? Why, it is simply this, that a medical man, if he does his duty by it—attends to the sick poor as he would himself wish to be attended, and visits them as often as is really adequate to the nature of the case, and gives as much medicine, and of the same expensive character, as he would prescribe for his private patients, (and this is the only way in which Unions *should be* attended,) he is inevitably a large loser by the contract. But he is generally a young man who cannot afford to lose, and what then is the alternative? Why he cuts down his visits to the minimum of what would be passable by the Board of Guardians;—and he gives as little medicine as possible, and that only of an inexpensive class—for he "cannot afford to give such expensive medicines"—and he quiets his conscience by some of the doctrines of "young physic," so plausibly and so opportunely set forth as a bonus upon inattention. Happily this *vis medicatrix naturæ*, aided by some appropriate diet, which the practitioner has it always in his power to direct from the board, in a great number of cases, puts the patient into a position for recovery. But is all this consistent with that high flown aversion to trade which is so constantly dinned into our ears? Rather, are not these principles the very maxims of trade Again, a young man obtains an union surgeoncy, starts in the appropriate locality, and hopes to make up deficiencies by his private practice. And how is this to be done? Why he starts by working *cheap*—by charging nothing for his journies and very little for medicine or attendance, and being young and active he can easily obtain credit for being very "*attentive*," and very "*reasonable*;" so he creeps on, riding over the heads of his neighbour brethren upon *the maxims of trade*. In my own neighbourhood I know several who pursue plans of this description, and one who is the perfection of his species—*(a double diplomatist)*—who attends midwifery patients during their confinement, and for a month afterwards, for a high fee of *five shillings*, medicines included. By these means he undersells all his neighbours, and even the midwifes; and to those who, like myself, have been accustomed to large fees, such a system, or even any approach thereunto, appears to be distinctly *suicidal*—and at all events forgetful of the gentleman. Added to all this, there are a thousand ways of making our brothers' mistakes or imperfections a stepping stone to our own reputation; and with these various arts we stand before the world as a trading community, and have become degraded in the eyes of the public; they undervalue our opinion thus too cheaply obtruded upon their notice, they prescribe for themselves, or they fall into the hands of designing quacks.

At a time when every man's income is diminished, and when the price of provisions, both for horse and man, is considerably reduced, there is, perhaps, a reasonable ground why patients should not continue to pay the old charges; but still medical men must live, —they must appear as gentlemen; they must bring up and educate their families; and if they live for the public benefit, and the public requires their services unreservedly when asked for, it is but reasonable that the public should support them adequately, so as to place them above the fear of want. The education of the present day requires a heavier outlay than formerly: hence, to avoid being trodden upon by the moral masses next immediately succeeding to our own position, our children must be more highly educated than heretofore; and the sources of good education have not as yet become so plentiful as to be also cheap.

As an intellectual pursuit the profession offers the most attractive advantages;—as a social position, it aspires to a grade which is satisfactory, and the medical man is, or ought to be, the friend of his patients; but as a commercial speculation there cannot be a worse investment of capital, and the same amount of capital invested in trade and commerce will produce far more available returns.

What, then, is to be done for the present state of the profession—and to avoid falling into the abyss over which we are beetling, and which is yawning beneath us? Our safety will not consist in legislative interference; no act of the Legislature can give us that title to public estimation, without which it is impossible to maintain our position. To obtain this position, we must prove ourselves worthy of it; and to effect this we must begin at the beginning—*early, or preliminary education*. It is a grievous, but notorious fact, that the education of our youths has generally been awfully deficient, and

that they are not only grossly ignorant of Latin and Greek, but thoroughly unacquainted with French and German, and ignorant of the first principles of science, which are essential to the character of an educated gentleman. This would form the basis of future improvement. Sexagenarians cannot expect it in their day, but those who come up to supply our vacant places may do so; and sexagenarian linguists blush at the present hour for the ignorance of the younger men. I would, therefore, that all young men destined for the profession be kept at school or college till they are eighteen; and that their attention be directed to obtaining a competent acquaintance with Latin, Greek, French, German, and Italian, as languages,—not simply to that which will give them a superficial acquaintance with those languages, but such as will enable them to read professional works in each, without the constant aid of a dictionary. Then, a certain acquaintance with mathematics is indispensable, as teaching young men to think clearly, and to reason accurately and consecutively,—to arrive at conclusions from foregone premises, and never to adopt a proposition which they cannot at least approximately prove. The study of natural philosophy, and a ready acquaintance with its sciences generally, should be considered as a *sine quâ non*; in addition to which, an acquaintance with the science of political economy, and with the philosophical history of Europe, and with the grand principles of mechanical and industrial science, should occupy the early years of the embryo aspirant of medical literature, before he ahould be considered as entitled to commence the study of a life-long profession. In this career, and in the examinations which should characterise its progress, the young man will have been taught to reason, to think, and read, as well as to record and to digest. The great evil of professional life is, that these qualifications have been almost always absent; that in courts of law a medical witness is generally known by the hardihood of his assertions, which at the same time he is utterly unable to defend or to prove. In conducting this preliminary education, the mind will have been brought out to *observe*—and *observation* is at the basis of all successful practice—*cæteris paribus*, the best observer being the best practitioner; for it is by the keen noticing of symptoms, and by the power of associating and classing these symptoms, and reasoning upon them, which escape the observation of others, that a man's real knowledge will best be tested.

Having arrived at his 19th year, I would suggest that that year be devoted to the acquisition of a knowledge of dispensing, and of analytical chemistry, with chemical lectures; not, however, forgetting the foregoing elementary instruction—but still keeping up, and enlarging the base over which it spreads. And now that the medical studies may be said to have commenced, I would take care that they be conducted in a *collegiate institution*—with collegiate rules—and under collegiate discipline and restrictions. I would not allow the present system of unrestricted license to young men, before they know how to use liberty without abusing it. Many a young man of fine promise is ruined by the dissipations and temptations of London, who, under a stricter supervision might at least be saved from the destroying vortex which whirls around him; and I would exert a great amount of vigilance upon these points, remembering that what I was now called upon to develop was a good and useful, well informed, well conducted, well principled, and kind-hearted character. I have mentioned dispensing as necessary in this stage of the tyro's education; not that I would devote any portion of time exclusively to the "art and mystery" of dispensing. But while the other branches of education were going on I would have as much attention paid to this subject as to make each young man fit for dispensing when called upon. During this year I would have the pupil attend a course of moral philosophy; and in the whole progress of education I would institute such frequent interrogative examinations as should test, not simply the memory, but the attention and acquisition, I might say the appropriation, of each individual.

Having arrived at the 20th year, I would now devote three entire years to the proper study of professional subjects, conducted still in collegiate institutions; after which should come the examinations for degrees, conducted, not as at present by a system of cramming and grinding, by which a young man with good memory and attention may always be made to pass, notwithstanding his previous idleness and carelessness; while another of high attainments—of unwearied diligence, and extensive knowledge, but nervous and diffident, as is always the case with true science, will incur a great risk of rejection; but so as to test the candidates' knowledge of first principles, and their application to practical emergencies. I suppose it is impossible *altogether* to do away with the system of grinding, or coaching, and so making up for past neglects by present assisted efforts; but as far as it were possible I would have this system altogether superseded. I am aware that by examiners it is said to be so now; but the contrary is well known to be the fact. The examinations at this period should embrace a far larger sphere of knowledge than is now required; for I would comprehend classics, modern languages, history, natural philosophy, mathematics, the fixed and applied sciences; in fact, such as to prove the man a man of ability and weight in the intellectual world, and entitled to rank among his compeers on a high scale.

It may be said that I have added very much to the expense of an already expensive education. I acknowledge it; and by so doing I shall greatly diminish the number of young medical men, whose friends would not invest their capital in so unremunerative a pursuit, or who had no capital or an insufficient capital to invest. But by so doing I shall have secured a better class of pupils; I shall have diminished the number of professional aspirants; and I shall have lessened that eager competition which results from the over-crowded state of the professional ranks; while I shall have secured a tribe of thinking young men, whose opinions will have *weight*, because of their very *thoughtfulness*, and who will be thus prepared for the science of observation on the one hand, and for that constant reading of profes-

sional works of their own and neighbouring countries, which will give them enlarged ideas, and enable them to extract all that is good and valuable from our continental neighbours, as well as from the narrower circle of home industry and research. It may be said that my views are visionary and impracticable. At any rate they are less visionary and impracticable than those which are dependent upon Acts of Parliament, because Acts of Parliament do not work upon the brain or mind, while my views are essentially operative upon the first principles of character, enlarging the calibre of that instrument which God has given us to be devoted to the good of his creatures.

There will be less chance than at present of men thus educated addicting themselves to quackery, because the enlarged mind will commonly recoil from the act of shrinking up itself into a capacity suited to the narrow requirements of the one-eyed monster; and there will be less chance of undue competition, because as the mind has been enlarged it will less readily yield to those paltry influences which operate upon little minds, and make them willing victims of the basest trickery in order to aid their selfish purposes. It must be confessed, however, that the "auri sacra fames" does produce a pestilential agency upon the minds of many from whom better things might have been expected; and that the facile road to wealth along the gilded causeway of quackery, without the anxieties and responsibilities, the cares or the privations of regular struggling, does present such attractive charms to many as to be irresistible. Over them we drop the tear of deep and sincere regret; and we weep over the pure and promising mind stranded on the rocks of exclusiveness, to which it has been lured by the *ignis fatuus* of gold.

Having now arrived at the age of 23, it will become a question whether the youthful Æsculapius should visit foreign countries, in order that he might see foreign practice. To this I should demur. Perhaps he has not the time to spare; and if he has we have already made provision for his intimate acquaintance, through the medium of books, with all that transpires among his medical or surgical neighbours. Hence, if he has time to spare that time will be *as* usefully, if not *more* usefully, spent by studying disease at the bed-side at home, and comparing his own observations with the records of disease from abroad. Let not the young man, in the pride of his country's practical pre-eminence, say that there is nothing to be learned from foreign countries. Their descriptions of disease are invaluable; their diagnosis of the keenest description, their pathology excellent, and their principles of practice, if frequently feeble, yet contain much that will be of the first importance to the practitioner. Especially in the departments of midwifery and surgery may their standard works be pre-eminently consulted. To find them undervalued is only to show an ignorance of their real treasures of knowledge, or the want of power to appreciate them; in neither case a very valuable attribute.

And now being fitted to enter upon practice with a great advantage over those who have had a more restricted education, and who are contented with daily routine, without looking after a daily increase to their stores of knowledge, they will carry with them the prestige arising from the weight of their literary character; and we may expect a corresponding *rectitude of conduct*. The influence of this latter principle will soon be developed towards patients, and towards professional brethren. To the former it will be shown in steadiness of effort to do them good, whether they be rich or poor—to study their character and comforts—to aid them in their difficulties—to direct their minds—to strengthen their feeblenesses—to assuage their fears—to guard them against imprudences—to become the sacred depository of their secrets—and to aid them in all the little emergencies of life, at once by counsel and by action. But the influence of this principle will equally be shown in not humouring their follies—in not saying as they say—in not falling in with all their whims, whether injurious or not;—or appearing to think as they think—or of being all things to all men, simply with the hope of pleasing them; but of always showing a front of unflinching integrity—a love of truth and justice, from which neither fear on the one hand nor favour on the other could induce the slightest deflection. That sort of plastic morality which is not infrequently met with is a constant source of degradation to the medical character. The patient has brains enough to see that he is only trying to please; and the result is that he is despised, his opinion considered as worthless, and the whole weight of his character is lost. How galling have I felt it to be told, "I have no faith in Mr. ——, because he has no opinion of his own. He wants to be told what *I* think upon the case, and then he falls in with *my* prescription; and if asked for a reason he has none to give." Let my brethren be assured that the loss of their influence is their own fault. Patients will not respect them if they do not respect themselves; they cannot respect themselves unless they form deliberate opinions, and are able to support them with reason; and they cannot form deliberate opinions unless they shall have had a good education, and shall have learned to think and judge for themselves, according as results through the successive stages of all but demonstrative evidence.

The fixed, and deliberate, and judicious opinion that is to be maintained with firmness, is very different from that captious irritability which leads the individual to take offence when his opinion is questioned, or when he is asked for the grounds of his judgment. Captiousness is the offspring and evidence of a weak mind, as well as a proof of the consciousness of that weakness, and yet it is from this feeble judgment that the patient's opinion is generally formed, and that the low estimate of professional character is produced; and then follows as a matter of course, a falling back upon one's own judgment, and becoming a prey to the most tempting or largely-promising quackery. Against this no Legislative enactment can be passed; but the remedy is in the hands of the practitioner. Let his opinion be only duly estimated, and he secures the confidence of his patient. It is indeed true, that in the long-con-

tinued maladies of patients who do not find themselves improving, their own judgment becomes weakened, and they will be apt to seek from largely-promising quackery what they find they do not obtain from more modest legitimate medicine, and it will be to the sorrow of the practitioner that he sometimes meets with successful effrontery where simple and real science has been foiled; but these will be *rare exceptions*.

Towards his brother practitioner the result of this improved education will be two-fold; first, to diminish the present over-crowded state of the profession, and as a natural consequence to lessen that competition which, in the present state, leads directly or indirectly into frequent collision of interests; and, secondly, by the cultivation of high-minded feeling, it will take away the frequent occasions of clashing interests and opinions, which give rise to bickerings and heart-burnings, and misapprehensions, while it would extend that benevolent feeling which consists in an abiding wish to do all the good we can, and which rejoices in a brother's success.

It will be seen, then, that the great panacea for the present ills which afflict us as a body, is improved education of our own minds; that *with this* we shall really require no legislative enactment; and that without it no Legislative enactment can possibly benefit us. Not that I would object to Legislative measures, which may in their place be necessary and desirable, but that I would enter a caution against relying upon them: what *these should be* I leave to others more conversant with the subject to consider and detail, provided they be not under forty years of age. I am only giving the result of my own observations during a not uneventful and a prosperous life of more than sixty years, and although for various reasons, I choose to say, in the celebrated motto of Junius, that—

"Stat nominis umbra,"

yet I enclose you my card, that you may know I am a real personage of some weight and influence,

And I remain, Mr. Editor,

Your faithful and constant reader,

Θεραπευτικος.

April, 1851.

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

CASES OF INJURY OF THE SHOULDER. BY W. J. MOORE, ESQ., M.R.S., HOUSE-SURGEON.

Fractures in the vicinity of the shoulder-joint require to be most accurately examined in order that a correct diagnosis may be formed. The neck of the humerus (anatomical or surgical), or portions of the neck and head, may be broken off; the glenoid cavity may suffer, or the neck of the scapula be the seat of mischief, and it is a most difficult thing for a tyro to diagnose between these varied accidents. The mistake of the case as regards the seat of practice would not probably be attended with any bad result, but should fracture be mistaken for dislocation, or dislocation for fracture, the patient will suffer inordinately, and at the best regain but a very imperfect power over the limb. It is, therefore, necessary that the symptoms of the different kinds of fracture, and particularly the differences between fracture and dislocation, should be attentively studied by every one who undertakes the duties of a surgeon; the position of the arm, the mobility, the absence or presence of crepitus, the position of the head of the bone, the manner in which the accident occurred, the flattening of the shoulder, and elongation of the limb all require consideration, and it is to the two latter symptoms more particularly that I wish to draw attention in the cases given below.

John Perry, aged 9, was admitted as an in-patient under Mr. Knowles, October 30th, having some time before fallen from a bench on the side and forearm. On examination, the shoulder was found *much flattened* and the elbow of the injured side *much lower* than its fellow, at first sight seeming much to resemble dislocation into the axilla. On manipulation however, crepitus was felt and the shaft of the humerus would roll independent of the head, while the parts were restored to their proper position by *raising* the arm, which indeed was required to be done ere the crepitation was audible. Some pieces of gutta percha were applied, and a pad placed in the axilla, the forearm being lightly supported by a sling under the idea that the muscles would, after recovering tone, sufficiently contract so as to bring the broken parts into apposition; this, however, did not prove to be the case, nor was it until the elbow was forcibly raised by the sling, that the fractured parts were in a proper position for union to take place. The boy was discharged cured November 21st.

As may be observed in this case, two of the principal symptoms of fracture were absent, and *vice versâ*, two of the principal symptoms of dislocation present. Had the patient been a stout person, the diagnosis would have been very uncertain, but being a child it was comparatively easy, particularly when the fact that dislocations rarely occur in children is also taken into the account. It is well to bear in mind that such anomalous symptoms may occur, and on this head Cooper observes:—"There may be a little depression or diminution of the rotundity of the shoulder, in consequence of the lower fragment being sometimes not displaced upwards, so as to produce a shortening of the limb, but on the contrary, drawn a little downwards by the weight of the part, so as to put the deltoid on the stretch, and thus in one respect, a degree of resemblance to a dislocation may be produced. On careful examination, however, the head of the humerus may be felt in the glenoid cavity, and the shaft of the bone does not offer that resistance to being moved about in various directions, which is experienced in a dislocation. In the latter case the head of the bone may generally be felt either in the axilla or under the pectoral muscles; in a fracture there is crepitus, but in a dislocation this symptom is absent."

The scapula being situated deeply and much protected by muscular parts, is not so liable to fracture as more exposed bones, and perhaps of all its parts, the acromion, from its more exposed situation, is most frequently injured; but the body of the bone, the coracoid process, and even the neck occasionally suffer, and although the latter part has been by some denied ever to have been the seat of fracture, yet there is no doubt that it occasionally happens, and the diagnosis in such cases is not made without some difficulty. The accident also is very liable to be mistaken for dislocation, some of the chief symptoms of the one being prominent in the other. "The diagnostic marks of this accident (says Sir A. Cooper) are three:—1st, the facility with which the parts are replaced; 2ndly, the immediate fall of the head of the bone into the axilla when extension is removed; and, 3rdly, the crepitation which is felt at the coracoid process when the arm is rotated." But the fracture may be either in front or behind the coracoid process, and if in front the difficulty of the case will obviously be increased, as we have not the grating sensation afforded by the pressure on the coracoid process, which part also is quite stationary.

Daniel Danter, aged 40, was admitted under Mr. Parker, July 27th, having some short time before fallen from a car seat on to the shoulder. On examination that part was found much flattened, the humerus intact, its head prominent, and in the axilla, and the elbow consequently lower than its fellow of the opposite side; hence the case presented the appearances of dislocation, still by raising the elbow the rotundity of the shoulder was restored, and on rotation a decided crepitus was felt deep in the joint; but pressure on the coracoid process alone did not give any sense of yielding or crepitation. Under these circumstances the case was inferred to be fracture anterior to the coracoid process, and as such was treated; a large pad being placed in the axilla, the shoulder kept back by a bandage, and the elbow well supported by a sling. In about twelve weeks he had very good underhand motion, but he had not when last seen, some months ago, acquired sufficient strength to attempt any exertion requiring the hand to be raised to the perpendicular.

Provincial Medical & Surgical Journal.

WEDNESDAY, MAY 14, 1851.

Many of our readers have doubtless at one time or other reflected with complacency on the advantages to be derived from the appointments of medical officers under the Health of Towns' Act, and when they may have got into their easy chairs, after a hard day, with inconsiderable profits, have thought how delightful it must be to be freed from the trammels of private practice and to hold an "office under Government." We would be the last to dissuade any one from the entertainment of so laudable an ambition, but before any of our friends take so decided a step, as is involved in becoming a health officer, we would have him acquainted with the following schedule of duties which he will be expected to undertake. If the perusal of them does not damp his ardour, we shall be much mistaken:—

"1. The general duties of the Officer of Health will comprise the duty of giving instructions and directions for the removal or prevention of causes of disease common to several persons, and also for the prevention or removal of causes of disease to individuals, where those causes come within the province of local administration under the Public Health Act.

"2. Except in cases where existing disease may be alleviated by the immediate removal of any of the hereinafter specified causes, the general duties of the Officer of Health shall in no case comprehend treatment for the cure or alleviation of disease.

"3. The Officer of Health shall take all practicable means to obtain the earliest information of the occurrence of cases of fever, of whatsoever type, of small-pox, measles, or other epidemic, endemic, or contagious disease.

"4. On obtaining information of the occurrence of cases of sickness or death from any such disease, he shall immediately visit the spot.

"5. He shall examine and ascertain, by house-to-house visitation or otherwise, whether others besides those who have died are affected; and he shall give such warning or instructions to the persons affected as may be calculated to induce them to have recourse to medical treatment, or take such measures as the circumstances of the epidemic or other species of disease may appear to require.

"6. In case of an outbreak of small-pox, he shall inquire whether any persons living in or near the premises are unvaccinated, and urge on the Guardians the duty of seeing that all unvaccinated persons are vaccinated under the 3 and 4 Vic. c. 29, and 4 and 5 Vic. c. 32, and take steps to discover unvaccinated persons, and secure their vaccination with the least possible delay. He shall also inquire under what circumstances the outbreak originated; carefully investigating the history of the first case, and the mode in which the disease was propagated. He shall inquire into and report upon the causes which have tended to impede the practice of vaccination, or to render the vaccination ineffectual, and the circumstances which may render re-vaccination desirable.

"7. In case of the occurrence of any epidemic disease amongst the occupants of any

single room occupied by one family, or by more than one lodger, or tenements otherwise overcrowded, the Officer of Health shall give instruction for the removal of the sick, or the diminution of the overcrowding, or for the prevention, by such means as may be available, of the spread of the disease.

"8. In the case of a death in any room occupied as a living or sleeping-room by survivors, he shall give instructions, either for the removal of the corpse to some house or place of intermediate reception, to await the funeral rites, or for the removal of the occupiers.

"9. In all cases of death, he shall give such instructions to the survivors as he may be authorized to give under any Act of Parliament, as to the care of the body, as to the sort of coffin to be used for the prevention of noxious evaporations, and the removal and interment of the body, with such precautions as may be required for the protection of the public health.

"10. He shall, after having given such instructions as aforesaid, in such order as he may deem necessary, examine into cases of typhus or other epidemic, endemic, or contagious disease, and inquire whether such disease was caused or aggravated by anything which is capable of removal in or about the premises, the living or sleeping-rooms, or places of work, of the persons attacked, and shall notify the same to the persons responsible for the nuisance; as, in the case of accumulations of filth, noxious cess-pools, house-drains, or sewers of deposit, to the officers responsible therefor: he shall also, where necessary, give instructions for lime washing, or the application of deodorizing or disinfectant mixtures or substances.

"11. In the case of small-pox or any other contagious or epidemic disease attacking any child who has frequented any school, he shall, as early as may be practicable, visit such school, and inquire and examine whether there be symptoms of the infection, or prevalence of the disease, amongst the other children, and give such instructions and advice as may appear to be necessary for the prevention of the spread of the disease.

"12. In the case of the like disease attacking any worker (whether young or adult) in any factory or place of work with others, he shall visit such place of work, and inquire and examine whether there be symptoms of the disease amongst the workers, and give such instructions or advice as may appear to be necessary for the prevention of the spread of the disease.

"13. Besides his own frequent visitation and inspection of those parts of his district which are the most likely to be the seats of disease, in order that he may ascertain as early as possible the actual occurrence of any form of zymotic disease, he shall maintain a constant communication with the inspector of nuisances for the district (whose reports he shall examine, and give such instructions thereon as will best ensure the speedy discovery of all causes injuriously affecting the public health), with the ministers of religion, the registrar of his district, and the Union medical officers, and shall from time to time examine the medical weekly returns, and the registers of sickness and mortality furnished by the district medical officers.

"14. He shall appoint and notify convenient times, at which, when not prevented by extraordinary duties, he will personally attend daily, or, at such times as may be convenient, at his office or other convenient place, to receive information in respect to the occurrence of epidemic disease or matters affecting the public health within the district.

"15. Inasmuch as the ordinary seats of epidemics are also the localities of other classes of disease which shorten life—such as scrofula, and its frequent concomitant pulmonary consumption, he shall further make a special examination of the conditions which produce a predisposition to this class of diseases, as well as to epidemics within the district.

"16. In his inspection of schools, manufactories, or workshops, he shall take note of the children, young persons, and work-people, who may appear to be pallid, feeble, sickly, or in a peculiarly low condition of health, and inquire whether such condition has been produced by over crowding, by defective ventilation, imperfect cleansing, or any other removable cause of debility or disease.

"17. He shall himself exercise such a superintendence over measures of prevention or alleviation which he may have recommended as will enable him to ascertain whether they have been properly and effectually performed; and if he find any deficiency or delay in the execution, he shall make inquiry into the cause thereof, and report the same to the Local Board of Health.

"18. He shall perform all the duties imposed upon him by any bye-laws of the Local Board, whether of inspection or otherwise, in respect of lodging and slaughter-houses, and any other matter affecting the public health in respect of which Local Boards may have framed bye-laws under the Public Health Act: and in visiting any tenements in pursuance of such bye-laws, he shall from time to time make such visits by night, or at such times as the inmates are assembled, and observe and report on the state and action of the means of ventilation in such places.

"19. Whilst public works of sanitary improvements or cleansing are in progress, such as the removal of cess pools for the formation of new drainage or sewerage works, the cleansing out of town ditches, water-courses, ponds, or

canals, he shall give such instructions as to the time and mode of conducting the operations, the application of water, lime, deodorizing or disinfecting substances, and any other means of protecting the public from noxious or offensive emanations as may appear to him to be requisite.

"20. He shall, upon any complaint, or upon the omission of any offensive or noxious smell, or the accumulation of deposits in drains or sewers, report upon the same to the Local Board of health, or to such officer as may be appointed by the Local Board to receive and act upon such complaint.

"21. On the occurrence of atmospheric pollution from any offensive process or trade carried on in any manufactory, yard, house or premises within his district, he shall inquire into the cause and report on the appropriate means for the prevention of such noxious smells and emanations. In the case of the refusal or neglect of the occupier or proprietor to adopt the measures recommended, or other effectual remedies, or in case of the manufacturing process being of such a nature as not to admit of any effectual remedy, he shall then observe and collect the evidence of the injurious effect of the process in question on health, shall be prepared to adduce such evidence whenever called upon by the proper authorities, and shall otherwise assist those authorities by all the means in his power in their efforts for the abatement of the nuisance.

"22. In cases where there is no medical certificate, or where, from anything that appears, the deceased died without any regular medical attendance, it shall be the duty of the officer of health to examine into and determine as closely as he may the cause, as well as the fact, of the death.

"23. In the case of deaths suspected to be from violence, accident, neglect, or carelessness, or when from other circumstances he may deem it desirable, he shall notify the same in writing to the coroner, and shall present a copy of such notification to the Local Board at their next meeting, and shall in all cases, where practicable, render such services as may be requisite to aid the investigations of coroners and magistrates.

"24. He shall attend at all meetings of the Local Board of Health, and report to them his proceedings during the intervals between their meetings.

"25. He shall keep a diary, in which he shall make an entry of his visits, and notes of his observations and instructions thereon, which diary he shall produce whenever required, both to the Local and General Board of Health; he shall also keep a register of complaints or representations made to him, to be called 'The Officer of Health's Application Book,' in which shall be recorded the date and nature of every application made to him, the date of its examination, and the result of such examination, and shall produce such book whenever required, both to the Local and General Board of Health.

"26. On the occurrence or discovery of any source of injury to the public health, or of any epidemic disease, he shall, besides warning the Local Board thereon, send information thereof to the General Board of Health.

"27. He shall, from the best information he can obtain, make a report not less frequently than once a quarter of the nature and amount of sickness and death which have prevailed during the quarter.

"28. He shall in such report describe the progress and effects of any works of amendment which may have been commenced or executed.

"29. He shall also prepare annually a printed report and tabular return of the ascertained sickness as well as mortality of the district for the year, distinguishing therein the sickness and mortality of the several streets, squares, courts, lanes, yards, and alleys; and for this purpose, where there is a survey of the district, he shall be furnished by the Local Board with a tracing or a copy of the same, on which he shall mark the seats of epidemic or other disease; and such report shall set forth the amount of epidemic sickness or mortality which has prevailed in the district, as compared with former years, amongst different classes of persons, and in different localities of the district, and also a comparison of such rate of sickness and death with the rates of sickness and death amongst other classes and in other places, and any instructions in the way of warning, or for prevention or mitigation of sickness, which the facts may suggest, as well as the particulars of any deaths which may have occurred from epidemic, endemic, or contagious disease, the amount and causes of infantile mortality (that is, of children under five years of age,) and the nature and amount of sickness and death which may have occurred from causes which appear to be preventible, and within the recognized province of public administration, or that appear requisite to be brought within it.

"30. The annual and quarterly reports shall be printed, and a copy given to each member of the Local Board, and two copies shall be transmitted to the General Board of Health, and one to the Office of the Registrar-General, and the Poor-Law Board, as well as to each member of the Boards of Guardians, and to each of the medical officers, and incumbents of the several parishes within the district; and it shall otherwise be circulated for the information of the inhabitants of the district, as may be provided by the Local Board of Health.

"Given under our hands, and under the seal of the General Board of Health, this twelfth

day of February, in the year of our Lord one thousand eight hundred and fifty-one.

"L.S. (Signed) "ASHLEY.
"EDWIN CHADWICK.
"T. SOUTHWOOD SMITH."

What the remuneration is to be for the performance of the onerous duties here recapitulated is not stated, but from prior experience of official liberality towards medical men, we are justified in believing that it will bear no due proportion to the responsibilities incurred. To discharge the requirements of the office properly will be no sinecure. A man must not only be an accomplished physician, but he must also be a chemist, toxicologist, something of an engineer, an astronomer, architect, and a natural philosopher in the widest sense; he must, besides, have a smattering of the undertaker about him, and should, moreover, be triply contagion proof, as in an ordinary sized town, he would on an average, inhale the emanations of typhus and small-pox for at least twelve hours out of the twenty-four. We are curious to see what the salary of such an universal genius will be.

Reviews.

A Practical Treatise on Diseases of the Urinary and Generative Organs, (in both Sexes) Part I. Non-Specific Disease. Part II. Syphilis. By WILLIAM ACTON. Second Edition. London: John Churchill, 1851. 8vo, pp. 693.

WHEN we consider that one in five of our military, and one in seven of our naval defenders are constantly under the influence of these diseases of the generative organs, and when we find that nearly one half of the out-patients of such a hospital as Saint Bartholomew's are in the same unfortunate position, we must admit the full importance of the subject to which Mr. Acton has devoted his attention. It is a common opinion that syphilitic diseases are gradually becoming less frequent, and that we may hope speedily to be rid of their presence among us; but this is shown by our author to be a fallacy, upon such evidence as is sufficient to support his assertion, and we fully agree with him that it is highly necessary to place the venereal patient upon equal terms with the sufferer from indulgence in any excess, whether in intoxicating liquors, in improper food, or in the venereal appetite.

The first part of the above treatise (which is so much enlarged as to be scarcely considered a second edition) is confined to the examination of the nature and treatment of what Mr. Acton calls blenorrhagia, generally denominated in this country gonorrhœa or clap, with all its attendant or consecutive symptoms, such as gleet, stricture, swelled testicle, spermatorrhœa, &c., and in the female also the corresponding inflammation of the vulva, urethra, vagina, uterus and ovary.

In this department Mr. Acton has been engaged in verifying the statements of Ricord, Lallemand, Bennett, and others, and he has presented us with the result of their labours, filtered through his own brain, and thus freed from much extraneous matter, and frequently illustrated and improved upon by the extensive opportunities which he has himself enjoyed in this country, as well as in the Parisian Hospitals.

There are so many interesting questions connected with these subjects, which are investigated by Mr. Acton, that it is impossible to do more than simply allude to them. The difficult task of deciding as to the origin of the particular attack which we have to treat, is one of those questions which most frequently teases the practitioner, and we shall therefore extract for the benefit of our readers, what Mr. Acton says upon that most perplexing case, viz., where a discharge having all the appearance of clap, comes on during the continuance of a connexion which has been going on for some weeks or months, perhaps even years, and when there is reason to believe that neither party has been unfaithful.

"Now, what answer can you give your patient, and what does all you have seen teach you?

"An examination thus made enables you tell your patient that the female from whom he has contracted the disease has been long suffering under the disease called "Whites," that it is this complaint which has produced the discharge in him, and your examination has given you no reason to believe that she has been unfaithful; in fact, as a general rule, the sexual desire in such females has been reduced to the lowest ebb, and infidelity is not one of their sins; but by degrees they have got into such a state that local treatment will alone cure the complaint, and treatment of indigestion will avail nothing.

"Your patient (and perhaps my reader) will ask, 'But why did not this occur in the commencement of the acquaintance? six weeks or more of cohabitation has passed, and it is only within a few days that I have had this disease, although I have exposed myself during the whole time.' And he will reply, 'You are attempting to screen this woman, who must have been guilty.'

"In the commencement of my private practice I had great difficulty in answering these pertinent questions; but, subsequently, I found the explanation easy enough; as long as these secretions from the female are destitute of pus, and the uterus and vagina are in that chronic state, giving rise to white discharges, as happens when connexion is not frequently indulged in, contamination will not probably occur; but if inordinate sexual intercourse, from strong constitutional power of the male, follows, inflammation is set up in the organs of the female, and, the secretion becoming purulent, contagion results; particularly if the man indulges freely in malt liquors, or has been taking violent exercise. Whatever be the true explanation, however, I am practically convinced of the fact, that contagion will occur a few weeks after constant cohabitation with females in the condition above described, although a man may escape at first.

"Now, if discharges can occur in males who have cohabited with females, can we be surprised if prostitutes communicate the disease to men, and yet on examination are not found to be suffering themselves from ought else than the whites?"

The complication of chancre with clap, is another point of great interest, first noticed by Ricord, and since illustrated by Mr. Langston Parker and Mr. Acton in this country. It will be found treated at length at page 57.

Under the head of "stricture," Mr. Syme's operation has been noticed, and its unfavourable results in this country recorded. Mr. Acton, however, does not appear to have *fully* made up his mind against this method of cure, but is strongly opposed to it from the experience which he has had of its effects. We find under this section, much useful information in small compass.

A section upon which great labour has been bestowed is that on "spermatorrhœa," in which we find a most able analysis of the larger and more diffuse work of Lallemand, well arranged, and though written in a forcible style, yet with as little disgusting particularity as the nature of the subject would admit. In the treatment of obstinate cases Mr. Acton suggests that when the application of solid caustic, as recommended by Lallemand, is unsuccessful, a glass syringe should be adapted to a short catheter, which should be passed down to the verumontanum, and the seminal ducts distended by a solution of caustic. We have never seen this plan tried, but as we have sometimes found the porte-caustique of Lallemand fail in its effects, we trust that Mr. Acton's suggestions may have the beneficial result which he anticipates.

Mr. Acton has not extended his observations on the diseases of the female organs to so great a length as we should have expected; but we think that for ordinary purposes every information may be found which is required for their treatment; and as Dr. Bennett's book has now become a necessary appendage to every surgeon's library, we can well spare a more elaborate treatise.

Under the second division of his treatise, viz., that of syphilis, we find a complete analysis of the writings of M. Ricord, which is a sufficient guarantee of the value of its contents. The fact that syphilis may always be tested by inoculation is here fully established, and also the observation first made by Ricord, that secondary symptoms once fully cured, can never re-appear in the same person as the result of a subsequent contamination. Indeed the whole subject is most ably treated, and we can only recommend all our readers who have to take charge of this class of complaints to study the theory of their development, as taught by Ricord, though they may find it necessary, perhaps, to modify his treatment to suit English constitutions, as has been done by Mr. Acton throughout his work. Altogether we cannot too highly recommend his treatise to our readers; it should be found wherever surgery is practised throughout the British empire.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

FEBRUARY 6TH, 1851.

MR. DUFTON IN THE CHAIR.

Necrosis of the Thyroid Cartilage; Œdema of the Glottis.—By Mr. HILL.

A PUBLICAN, aged 39, of spare habit, and very temperate, called on Mr. Hoare, in December, 1847, complaining of difficulty of breathing, loss of voice, and a tickling cough, which symptoms were relieved by an irritating plaster to the chest and a blister to the throat, &c.

In June, 1849, he again applied with similar symptoms, but somewhat aggravated, and was again relieved by similar treatment.

In July, 1850, Mr. Hoare saw him again, and he remained under treatment until December 8th, 1850., when he died. During the last month of his life he had difficulty of swallowing; he experienced the greatest relief from repeating the blister to the throat.

Upon examining his chest after death, we found the lungs studded with tubercles, which had softened at the apex of each lung, where there was also a small cavity.

The glottis and part of the upper margin of the larynx œdematous and much thickened, and there was necrosis of a small portion of the left side of the thyroid cartilage.

Apoplexy of the Pons Varolii.—By Mr. Hill.

Mary Mollineux, a woman of very intemperate habits, the mother of seven children, the last illegitimate, who had always enjoyed good health, had been at work baking, came home and partook of a hearty meal of bread and cheese and onions, during which she was suddenly taken ill, and by the time she was carried up stairs she died. This was in about ten minutes. She spoke once after the seizure, saying she felt as if about to die. On examining the body twenty-four hours after death, a small clot of blood was found in the pons varolii, about the size of a nut, the other organs were healthy, excepting the right kidney, which was not larger than a pigeon's egg.

Tubercular Peritonitis; Tubercular Pericarditis, with Universal Adhesion, and great Hypertrophy of the Heart; Lungs quite Healthy; large solitary Hydatid in the Liver, containing multitudes of Echinococci.—By Dr. Russell.

Charles Beesley, aged 35, married; nightman. He died January 25th, 1851.

Sectio-cadaveris fifty hours after death.—Body not much emaciated; the serum in the cellular membrane tinged with bile. *Abdomen:* The intestines closely adherent to the wall of the abdomen, and completely packed into one mass by firm adhesions, which contained abundance of tubercular spots, many of the diameter of a split pea. The liver adhered closely to the diaphragm and to the stomach; it was healthy, except that the lobulus quadratus was entirely converted into a *large tumour*, which advanced in front beyond the acute margin, so as to have been felt during life, and reached behind nearly to the obtuse margin of the organ. The gall-bladder was healthy, and contained some brownish thick bile. Unfortunately the ductus communis was lost in the difficult dissection. The tumour was found to be an immense cyst, occupied by a single large hydatid, containing twelve ounces of fluid. The cyst was perfectly closed; it was lined by a dry hard layer of inspissated bile; it was very dense. The hydatid was composed of a sac, an eighth of an inch thick, and in appearance and tenacity closely resembling coagulated white of egg. The fluid of the hydatid was perfectly limpid; it contained a very large number of small round white bodies, like small poppy seeds, which fell to the bottom in a thick layer, some, however, adhering to the side of the bottle with considerable tenacity. The fluid had a specific gravity of 1008, was neutral, and unchanged by heat and nitric acid combined. The round bodies were found by the microscope to be groups of a large number of echinococci, connected together by a distinct substance. In some groups I counted twenty-three individuals. The parasites all had their spines retracted, and at the lower extremity of the body of some was a kind of pedicle, rather broad but short, and of very loose texture. length of echinococcus 1-125th of an inch. The general tissue of the liver was dark, very compressed, and with an unusual distinctness of the white elements, which seemed thick and hypertrophied. Spleen diffluent. Kidneys and pancreas healthy. Between the cardiac extremity of the stomach and the spleen, was a large cavity enclosed in the peritoneal processes, containing pus; it extended down to the pancreas, which, however, was quite uninjured. This cavity was covered internally by pellets of a yellow cheesy substance. The great omentum was completely gathered up in a dense thick mass of very firm consistence, but its section displayed the fat pellets, and without a trace of tubercle. The interior of the stomach was coarse, and dark coloured; towards the cardia were patches of dark vascularity. Unfortunately we were unable to stop to dissect the intestines, so that they and the mesenteric glands were unexplored. *Chest:* The pericardium was enormously thickened. It adhered to the heart at every point; the adhesions admitted of being torn through; they were very abundant, in parts reticulated, but tolerably soft. In front (chiefly) they enclosed tubercular spots in abundance. At the base of the heart the bronchial glands were, many of them, much enlarged, and converted into a cheesy matter. In opening the left auricle an extensive deposit of caseous matter was exposed, lying apparently in an extensive thin patch between the false membrane and the auricle. The heart was enormously hypertrophied, and very considerably dilated. The lining membrane of the cavities was healthy. Valves healthy; the mitral hypertrophied. The tricuspid orifice admitted four fingers abreast; the mitral three. The tissue of the heart was very pale and flabby. The lungs healthy throughout, except that their tissue was much congested, and of a florid tinge, but it crepitated. We could not discover *a single tubercle* in their tissue. They were perfectly free from adhesions, except that the right lung was attached to the pericardium by not very firm lymph.

By the microscope.—The pericardial adhesions contained an abundance of fat in vesicles of various sizes, dotting the bands of fibrin, and apparently connected with them, as comparatively few floated free. The thickened omentum presented abundance of healthy adipose tissue. The pellets from the interior of the abscess near the stomach, no fat, not entirely composed of granular matter, some of which had the appearance of very small cells. The liver-cells small, very dense, and contained fat, and a good deal of darker matter in irregular globules, apparantly of a fatty character. Heart-fibres healthy.

History.—He came under my care December 13th, 1850, having been under Mr. Welch since Nov. 10th. I found him deeply jaundiced; his urine greatly loaded with bile; he had a little pain in the abdomen; he had suffered severely from this pain especially in the hepatic region, but this had subsided; in the situation of the right lobe of the liver was a hard prominence, occasioned by the tumour.

From his history I learnt that he had not been well for nearly two years, but he dated his present illness to the beginning of the year. He had previously suffered a good deal from pain in his abdomen. At the beginning of the year jaundice came on. He then was under the care of Coffin, the herb doctor, and was dosed with cayenne pepper for four months. His bowels were very loose, and he had frequent pain in his epigastrium. At the end of the four months he called in Mr. Field. He was then salivated, but the jaundice did not subside at first. He subsequently got better, and returned to his work for twelve weeks, the jaundice having subsided. At the end of that time he again became ill, the jaundice returned, and he procured a dispensary ticket. When Mr. Welch first visited him there was a considerable quantity of fluid in his abdomen; this had become absorbed under the influence of mercury cautiously administered. He was a fine-made man, and considering the length of his illness, in tolerable condition. The further history does not present much matter for observation; neither by his history nor by his symptoms was the least suspicion excited of the extensive thoracic and abdominal disease, beyond the presence of the tumour in the liver and evident enlargement of the heart, though from what cause I could not discover. He had never had rheumatism. On two occasions only had he even irregularity of the pulse. On the 14th of January I found him considerably exhausted; I found that he had been bleeding at the anus for a week, and the last two or three days very profusely. The hæmorrhage did not, however, return, but in its place a fresh symptom arose—most profuse perspirations night and day, and continued to the time of his death, unchecked by full doses of sulphuric acid.

On the 25th, on visiting him, I found him suffering from collapse, with extreme dyspnœa. No more hæmorrhage had occurred. His chest-sounds unaltered. He died the same evening. He did not inherit consumption.

The entire absence of any symptom in his history leading my attention, either to the chest or the abdomen, except the diarrhœa which had long since ceased, and might have been caused by Coffin's medicine, and the presence of undoubted disease in the liver, rendered a suspicion of the extensive disease found after death impossible. The healthiness of the lungs, too, prevented any hint being afforded from their condition. The perfect absence of any sign of cachexia in his appearance, (for he was even in good flesh,) would almost have neutralised any suspicion tending to the disease, and combined with the pain and tenderness described, and the diffused feel of the tumour, confirmed my belief of the inflammatory nature of the hepatic disease, against which the absence of gastric derangement was the only sign.

That all this disease should have occurred without any symptoms sufficiently prominent to impress his memory is extraordinary, more especially as from the softness of the cardiac adhesions, they could not have been of long standing. His habits, from his own account, were not very intemperate, and doubtless the exposure involved in his trade, had a powerful influence in originating the cardiac and intestinal disease.

A peculiar growth of Fibrous character from a small portion of the interior of the Dura Mater, in an Epileptic Patient.—By Mr. Burbury.

The patient, a male, after suffering for some time from headache, became the subject of epilepsy, about a year and a half ago. On January 24th, he fell, his forehead coming in contact with a corner of the table; he was soon after seized with convulsions, which continued with slight intermission till his death.

January 29th.—The deposit corresponded to the left frontal eminence; the cerebral tissue around and beneath, was softened and diffluent; the arachnoid over the hemisphere were opaque; and there were about two ounces of fluid at the base of the brain. The dura mater, at the part mentioned, presented externally roughness and some increased vascularity; internally, a diseased surface of irregular shape, but about two inches in extent, longitudinally and transversely; the appearance of the diseased patch, was just that of a mucous membrane grown upon the dura mater; the surface was smooth and glossy, and had just the aspect of the intestinal mucous membrane thickened. At the circumference the disease terminated in elevated irregular granulations, some of considerable size—about that of a horsebean; the thickened circumference was partly separated from the dura mater, but the deposit could not be raised further. Towards the edge the diseased patch presented streaks of vascularity, and was of a rosy hue. On dividing the diseased portion, it was shown to consist of a thickening of the dura mater; it was about a line and a half thick; it cut very firmly and the section showed identity of tissue with the subjacent fibrous membrane. The glossy inner surface seemed due to a less fibrous layer, which, however, could not be raised, and which, by scraping, lost a scanty portion of rather pulpy matter, not unlike mucus. The granulations were very hard and crisp; when divided, they displayed a semitransparent fibrous tissue, not very vascular, containing distinctly defined portions of yellowish white, not unlike tubercle in appearance, but as hard and crisp as the rest. The impression received from the first sight of the portion, was that it was of fungoid nature, it closely resembled such a growth, though not sufficiently vascular; its firmness, and above all its microscopic characters, contradicted the assertion. The microscope proved the diseased structure to have a strictly fibrous character—like the tissue of fibrous tumours. The arachnoid membrane had disappeared in the part corresponding to the disease, the diseased portion being in contact with the brain, which, as described above, was disorganized in that part.

Foreign Department.

FRANCE.

PROCEEDINGS OF THE FRENCH ACADEMIES.

ACADEMIE DE MEDECINE.

The sittings of this learned body for the present year commenced with the demonstration by Dr. De Courtz, of Montpellier, of a new instrument for the extraction of certain foreign bodies from the bladder, with a lengthened account of its uses, which has subsequently been published in the February number of the *Archives Générales*. It is not possible to describe this instrument with accuracy without the aid of the plate by which the essay is accompanied, but it appears to consist of a canula, through which passes a sound, having a hook at the end, by means of which certain bodies, as pins, &c., are drawn into the canula, and extracted. The plate figures a large pin which was thus extracted from the bladder of a soldier.

Two reports were produced at the next meeting, one "On a Case of *Urethral Fistula* in a Female," by Dr. Colson, the other "On the *Treatment of Hydrocele by the Injection of Ammoniacal Gas*," by M. Bonnafont. M. Robert, who read the paper, noticed that the pain of the injection is severe, but the inflammatory symptoms are mild and transitory. In eight cases thus treated, all seemed at first to be successful, but relapses took place in six. Comparing the gaseous injections with those of iodine, which are so generally successful, and so rarely followed by untoward consequences, M. Robert does not hesitate to pronounce in favour of the latter.

M. Lesauvage narrated a case in which he divided the tendo-Achillis for reduction of a fractured astragalus.

M. Chailly-Honore read a "Memoir on *Premature Birth, and the means of Reducing the bulk of the Fœtus at the full Term.*" In this paper he discusses the comparative value of premature delivery, and a debilitating regimen, with repeated bleedings, for the purpose of stinting the growth of the fœtus. He decides that the latter project is irrational and uncertain.

M. Lepelletier presented an "Essay on the *Physiological and Pathological Effects of Brucine.*" Among the former the author notices various nervous symptoms, resembling electric shocks, affecting chiefly the muscles of the extremities. There is also great wakefulness, headache, loss of sight, &c. The therapeutic effects are shown in paralysis not depending upon myelitis.

ACADEMIE DES SCIENCES.

This Academy has been chiefly occupied with the consideration of anæsthetic agents, and more particularly of one called by the French *Ether Chlorohydrique Chlorèe*, the Dutch liquid with excess of chlorine. This has been found extremely useful as a local anæsthetic, chloroform being all but inadmissable for that purpose, on account of the burning sensation which its contact with the skin induces. M. Fleurens has instituted experiments with this fluid, and M. Aran has also recorded his observations referring to local anæsthesia. The result is, that he has found the use of this fluid of immense service "in every case in which there is acute pain, whether the pain itself constitutes the disease, or whether it is only a symptom." The diseases in which he has chiefly employed it are, articular rheumatism, neuralgia, colic, &c.

This preparation is made by an excess of chlorine in hydrochloric ether. It has a sweet fruity flavour and smell, does not act on turnesole paper, and is inflammable. It is sprinkled on lint, and applied to the painful spot, covered with oiled silk. It may also be used as ointment, one part to two and a half of lard.

Among other memoirs presented during the month of January, we may mention — 1. An essay by M. Arneth, "On the *Method of Preventing Puerperal Fever in use at the Maternité of Vienna*," which consists in making all the pupils and attendants wash their hands in a solution of chloride of lime. 2. A memoir "On *Puerperal Fever*," by M. Devilliers. 3. A "Case of Hemiplegia induced by Bleeding."

Nature of Chorea.

Dr. Botrel, in his inaugural thesis, has adopted the opinion that chorea is essentially of rheumatic origin, or rather a variety of rheumatism attacking the nervous centres. He has had the candour to admit that the same ideas were previously made public by M. See, but does not seem to be aware that the rheumatic nature of chorea has been some time since recognized by British writers.

Hydropathic Treatment of Anæmia.

M. Fleury, (*Archiv. Generales,*) who, unlike the tribe of "water doctors" who infest this quack-fancying country, appears to make a really scientific use of the therapeutic powers of cold water, informs us that all forms of anæmia are rapidly cured by the cold douche. The cases in which he is successful are those in which the lymphatic temperament originally predominates; cases of chlorosis which have resisted steel and other appropriate measures; anæmia from loss of blood, unwholesome occupations, marsh miasms, &c. We can readily believe M. Fleury that in the majority of such cases little is required beyond plenty of fresh air, wholesome food, exercise, and a cheerful tone of mind. The cold douche will doubtless, by aiding and fortifying the capillary circulation, materially assist the other ingredients in the regimen.

On Primary Amputation in Gun-shot Wounds.

M. Rastelle, (*Annali de Medicina,*) one of the surgeons of the Sardinian army, after a close analysis of the surgical practice during the last campaign, confirms the opinion generally held by military surgeons, that primary amputations are much to be preferred to secondary operations in gunshot wounds. By primary amputa-

tions he means amputation performed within six and thirty hours of the injury. He refers to twenty-six operations of this kind, twenty of which were successful. Of these, ten were amputations of the upper arm, one of which died; fourteen of the thigh, with five deaths. On the contrary, of twenty consecutive operations fourteen died. Thus in primary operations it appears that the mortality is twenty-four per cent., while in consecutive amputations it is as great as seventy per cent.

GERMANY.

Borax as an application to Gangrenous Buboes.

We find that Dr. Effenberger (*Journ. für Kinder Krankheiten* stated at a meeting of the Vienna Medical Society, that he had applied a solution of borax, in the proportion of from one to two drachms in a pint of water, to a large number of patients who suffered from gangrenous bubo, with great success. He had had fifty cases in one year; not one had died, although there were several very severe cases, and in one the femoral vessels were laid bare. The solution was applied by means of charpie, so as to cover the edges of the sore. It was very essential that the charpie should be very frequently renewed by night and day, and to the neglect of this precaution he thinks is to be attributed the failure of this practice in the hands of other surgeons.

General Retrospect.

ANATOMY AND PHYSIOLOGY.

On the Parovarium of the Female, the Analogue of the Epididymis in the Male.—By Professor Kobelt.

The *Wolffian* bodies are generally believed to be peculiar to intra uterine life, and to disappear in both sexes without leaving any trace of their existence. The author, however, affirms that it is possible to demonstrate anatomically, that these organs in both sexes, generally regarded as temporary, continue throughout life, and that they do not begin to waste until after the cessation of the generative functions. The following paragraphs contain the pith of this interesting essay:—

1. In the earliest periods of intra-uterine life there is no distinction of sex, the elements of both sexes in fact existing in every individual.

2. The "generative gland" may become either a testicle or an ovary.

3. By means of the excretory ducts of this gland, that is to say, by the *Canal of Müller* in the female, and the excretory duct of the *Wolffian body* in the male, each embryo assumes the attributes of one or the other sex.

4. The sexual difference consists in the development of one of these ducts, and the arrest of development in the other.

5. In the male, the Wolffian body does not disappear entirely, but it constitutes in chief part, the epididymis; its cul de sac forming the *coni vasculosi* of the epididymis.

8. The superior culs de sac of the excretory duct of the Wolffian body become effaced, or converted into hydated vesicles. The inferior culs de sac also disappear, or are converted into *vasa aberrantia Halleri.*

7. The excretory duct of the Wolffian body forms the canal of the epididymis and vas deferens.

8. In the female the Wolffian body never entirely disappears, but it contributes to the formation of a new body, discovered by Kobelt, and called by him the *parovarium.* This body is placed between the ovary and the fallopian tube.

9. The culs de sac disappear or become *coni vasculosi* as in the male, others become the vesicles so often observed in the fringes of the fallopian tube; others, again, the inferior ones, disappear altogether.

10. The excretory duct of the Wolffian body is arrested in its development. The duct of Müller becomes the fallopian tube.

11. Hermaphrodism is caused by the persistence of all the elements of the generative tissues.

[In connexion with the above we may append the conclusions respecting the Wolffian body extracted from an inaugural thesis, by Dr. Follier.]

The Wolffian bodies are developed in two distinct portions on each side of the spine, originating in special organic cellules, and not as an expansion of either of the allantois or of the vesicula umbilicalis. The generative gland (either ovary or testicle, as the case may be) is formed quite independently of the Wolffian bodies. These bodies are formed of tubes, at first straight, but afterwards becoming tortuous, and ending in an excretory duct. The excretory duct of the generative gland is developed independently of that of the Wolffian bodies, which bodies are not completely effaced at birth. In the female they persist partly in the form of small canals situated in the broad ligament, near the ovary, and in some instances appear in small cysts. In the male the remains of the body are found near the head of the epididymis, and consist of small diverticular canals, the *vasa aberrantia Halleri*, and the hydatid of Morgagni. The author denies that, as Kobelt asserts, the canicules of the Wolffian body forms the vasa efferentia of the testicle.—*Recherches sur les Corps de Wolf*, 1850.

MEDICINE.

Treatment of Organic Disease of the Heart.—By Dr. Scott Alison.

The principles upon which Dr. Alison treats organic disease of the heart are these:—1st. The abatement of inflammatory action when present by leeches and counter-irritation. 2nd. The abatement of inordinate action by harmless sedatives, as hyoscyamus, conium, and lactucarium. When quieting was required at the same time that a tonic was necessary, hop was found of advantage. When vigor was wanted, and there was no extreme irritability, iron was found to afford lasting benefit.

When congestion occurred, the secretions of the organ affected were solicited, if a secreting organ; if the head or lungs were affected, blood was taken locally. When violent palpitation occurred, with pain and dyspnœa, morphia was called for, and acted well. Dropsy demanded much attention; when due to direct cardiac obstruction, saline purgatives and diuretics were administered; when it was due to debility, as in advanced cases, more stimulating diuretics were demanded.

In these cases where the dropsy depended on secondary visceral congestion, the removal of the latter is to be attempted by leeches and mercurials. Tapping and puncturing are resorted to under special circumstances. The author prefers small incisions to punctures in anasarca.

When œdema of the lungs is threatened, the combination of squills and blue pill is found most serviceable. The author has found urine to be copiously secreted as soon as mercurial action is established, though all forms of diuretics have previously failed.

The stomach presents some disorders for rectification. Irritability and vomiting required treatment. When ordinary remedies failed, ices were had recourse to with extraordinary benefit. It is considered by the author to be highly important to keep the heart in a state of good muscular tone, for this purpose he recommends a liberal diet, pure air, tonics, and especially the preparations of iron. The recumbent posture should also be frequently assumed, in order to lighten the labours of the weakened organ.—*London Journal of Medicine*, April, 1851.

Diagnosis of Hæmatemesis.—By M. Valleix.

1. *Distinctive signs of hæmatemesis and epistaxis.*—

Hæmatemesis.	*Epistaxis.*
Symptoms referable to the disturbance of the digestive organs.	No such symptoms.
Vomiting of blood not preceded by nasal hæmorrhage.	Nasal hæmorrhage precedes the vomiting of blood.
No traces of blood in the nasal fossæ.	Traces of blood, either fluid or clots, in the nostrils.

2. *Distinctive signs between hæmatemesis and hæmoptysis.*—

Hæmatemesis.	*Hæmoptysis.*
Black blood in soft or broken clots.	Blood commonly red and frothy.
Blood rejected by vomiting after nausea, epigastric weight, &c.	Blood rejected by coughing.
Dulness of the epigastric region.	No dulness in this region.
Food mixed with the blood.	Blood pure or mixed with other expectoration.
Fœtid dark stools follow the vomiting of blood.	Natural stools.
No sub-crepitant râle.	Sub-crepitant râles.

3. *Distinctive signs between idiopathic and symptomatic hæmatemesis.*—

Idiopathic hæmatemesis.	*Symptomatic hæmatemesis.*
Digestion not disturbed.	Prolonged disturbance of the digestion.
No obvious emaciation.	Extreme emaciation.
No epigastric tumour.	Epigastric tumour

4. *Signs that the hæmorrhage continues after vomiting has ceased.*—Weight, fluctuation, and pain in the epigastric region; coldness of extremities, rigors, cold sweats; sinking and faintness; small thready pulse.—*British and Foreign Medico-Chirurgical Review*, April 1851.

On the treatment of Disease in the Aged.—By Dr. Nichols, U.S.

The following remarks occur in an address to the New Jersey Medical Society. They are worthy of remembrance:—In the treatment of disease in the aged, we must keep in view certain principles, founded upon the pathological conditions alluded to in another part of this essay. If this period of life be marked by a decrease of vital energy, less resistance will be offered to the assault of the disease; inflammatory affections will be found to be more rapid in their course, and if severe in character, have a fatal issue. Therefore remedial means, to promise success, must be employed early. Again, these remedial agents, if calculated to lower the powers of life, must be employed cautiously, lest the resistance offered by the vital forces be rendered still more feeble, if not entirely extinguished, by means appropriate in themselves, but injudiciously used. In the aged, particular regard must be had to peculiarities of temperament, previous habits, constitutional infirmities, condition in life, and the effect of other known causes which influence disease. But, as a general rule, in this class of persons depletion must be cautiously employed; and under this term I include not only bloodletting, but all those remedies calculated to lower the vital forces, whether in the nervous or circulatory systems. When venesection is carried to any considerable extent, its effects should be carefully watched, lest fatal exhaustion should ensue; and if cathartics are employed, it may be proper to exhibit them in combination with some aromatic or stimulant, and closely observe their action, lest it be too energetic or too protracted. In the use of all such remedies, due precaution should be observed, lest in our endeavours to eliminate disease we waste all the constitutional energy necessary for its successful resistance! The young and inexperienced practitioner who attacks the maladies of the aged heroically with the indiscriminate use of the lancet, antimony and calomel, may have the misfortune of witnessing his patients arriving at their allotted boundary, as it is called, in a much shorter period than if left to the care of nature and a judicious nurse. The strength of the aged patient must be sustained, in some cases, by a restorative regimen, and by nutritious aliment; by a due attention to warmth, both of clothing and apartment; and in convalescence, by the judicious use of agreeable tonics and cordials. In this stage of life, the depressing passions exercise a strong control

over disease; it becomes, therefore, our duty to guard against them. Youth is proverbially buoyant and full of hope; manhood is too much absorbed in its pursuits and plans to yield its hold on life without a vigorous struggle; but old age is apt to be despondent, and oppressed with the conviction that each assault of disease is a new summons, bidding him prepare to obey the inevitable law of his being. While the truth is not to be withheld where the issue is evident, in all doubtful cases and especially where the aspect is favourable, powerful auxiliaries will be found in all those encouragements and assurances, calculated not only to produce calmness and cheerfulness, but also inspire hope and confidence.—*Boston Medical Journal*, Feb. 1.

SURGERY.

On Post-Aural Tumours.—By Mr. Wilde.

Tumours behind the ear, and in any way connected with the mastoid region, demand the immediate and special attention of the practitioner. The author specifies five kinds of post-aural tumours, the situation and characters of which every surgeon should be acquainted with, as some of them may prove fatal in either the acute or chronic form. There is a small gland lying upon the mastoid process immediately above the insertion of the sterno-mastoid muscle, and on a level with the tube of the ear, which sometimes enlarges to the size of an almond; it becomes highly irritable and painful to the touch, so as occasionally to resemble a neuroma. It generally occurs in young females. The author mentions one such case which he attended some years ago along with Dr. Graves, and it was so painful that the lady could not bear to have it touched. The external application of iodine, and the internal exhibition of tonics, particularly iron, will in time remove these glands, but they are always very tedious. The second form of tumour is also glandular; it is simply a suppurating gland, and is not unfrequently met with in young children during dentition. It generally appears in scrofulous constitutions, and very often in persons who have suffered from some inflammatory action in the middle ear or the external meatus. The author states that he never saw one of these suppurating glands, the great bulk of which was not below the level of the external meatus, and this is a diagnostic of some importance, as a very formidable and often fatal swelling, which sometimes occurs behind the auricle, is always seated higher up. The third form of tumour he has only seen upon two occasions; it is a chronic abscess, very similar to lumbar abscess, and is, like it, generally connected with diseased bone. He alluded to a little boy at the hospital, about three years ago, who laboured under this disease upon both sides. Each tumour was about the size of half an hen-egg, fluctuating, painless, and occupying all the space behind the auricle; the skin nearly of the natural colour, but traversed by several blue veins. These tumours were opened, and from each of which poured a quantity of the usual scrofulous curdy matter. Almost the entire of the surface of each mastoid process was denuded, and rough. The abscesses filled several times, the child's health gave way, hectic ensued, and it died with cerebral symptoms. The fourth form of tumour is the result of acute inflammation, either arising from periostitis of the post-aural, and often extending over the entire parietal region, or caused by accumulations of matter in connexion with disease of the mastoid process, the result of tympanitis spreading from the middle ear, or from chronic inflammation and otorrhœa producing caries, which extends into the mastoid cells; and with this external manifestation we sometimes have diseased action of a sudden and fatal nature going forward within the cranium, in the inner table of the skull, the membranes of, and even the brain itself. The fifth tumour which occurs in this region is a malignant fungus, of which the author has seen three cases: one in a boy aged 10, the others in adults who had passed 50. —*Medical Times*, April 12.

Mr. Wakley's New Instrument for Stricture.

Here is another proof of the adage, that "there is nothing new under the sun." Mr. Courtenay writes to the *Medical Times*, to state that he some time since had devised instruments similar to those advertised by Mr. Wakley, as original. He says:—

"Many years since I had a silver catheter made, with a removeable thumbscrew attached to it, and a directing rod to screw on to the external extremity of the catheter after its introduction to the bladder, and both solid and flexible tubes, for the purpose of passing them along the directing-rod and catheter through the strictures to the bladder, and thus to dilate the contracted urethra. Immediately on the first appearance of the account of the supposed new instruments in your journal, I went down to Messrs. Weiss, and requested to be shown them, stating that I thought, from the description, they resembled mine. On seeing them, I found the catheter and its apparatus perfectly similar. The flexible tubes were the same, but the silver were much better made than those which I had used. I at once returned home, had a search for my instrument, and having found the above described catheter and its apparatus, with a flexible tube, I went again to Messrs. Weiss and submitted them to their inspection, when they at once acknowledged the resemblance between the instruments, and expressed their regret. This was on Saturday, the day of publication. On the next day, (Sunday,) I called on Mr. T. Wakley for the purpose of showing him my instruments. I did not, however, see him. On the same day I had to call upon Professor Furgusson on another matter, and I took the opportunity of showing them to him. A day or two after this I wrote to Mr. Thomas Wakley to inform him of the object of my visit on the Sunday, and at the same time to offer to show him my instruments, if he liked to call upon me. After an interval of nearly a week, I received an acknowledgement from him of the receipt of my communication; but, as he did not or would not appear to understand the object of my letter, I wrote him a second distinctly telling him I had long since, in all essentials, forestalled his idea and instruments. To

his communication I have never received any reply. Since this Mr. Gay has seen my instruments, and was perfectly astonished at the entire similarity of Mr. Thos. Wakley's catheter."

To this letter the Editor of the *Medical Times* appends a note to the effect, that neither Mr. Wakley nor Mr. Courtenay are entitled to the merit of originality, the claim, in fact, resting with Dr. Buchanan of Glasgow.

Spontaneous Collapse of the Antrum.—By W. White Cooper, Esq., F.R.C.S.

This rare case occurred in the person of a robust female, aged 25. Her appearance was remarkable; there was a deep purple depression between the side of the nose and the malar bone on the left side, looking precisely as if a portion of the maxillary bone had been removed. The depression was bounded above by the inferior margin of the orbit which partook of the depression, inferiorly by the alveolar process and malar bone, and in the centre by the nose. The distance from the bridge of the nose to the bottom of the depression, was an inch and four-tenths.

Until seven years previously her face had been symmetrical, but about that time she perceived a dusky mark beneath the left eye, unattended with pain. This mark gradually extended, and some flattening of the cheek became perceptible; this gradually increased until the face assumed its present appearance. A week ago some stillicidium lachrymarum ensued.

Her teeth were *in situ*, but greatly decayed, and the gums were in an unhealthy state, but the alveolar process was sound.

Mr. Cooper has failed to find any account of this singular affection in the records of surgery, the only approach to a reference to it being in Otto's "Compendium of Pathological Anatomy." Nothing is suggested to remedy it by Mr. Cooper or Mr. Fergusson, who saw the case.—*London Journal of Medicine*, April, 1851.

TOXICOLOGY.

Poisoning by Chloroform taken Internally.—By Alfred Taylor, M.D.

A young man, aged 22, entered a shop at 2 P.M. and fell asleep. No notice was taken of him for two hours, when, as he could not be roused, a surgeon was sent for. Mr. Gleadale, who attended, found him comatose, cold, with insensible pupils, small pulse, and breath strongly impregnated with chloroform. An empty four-ounce bottle was found in his pocket.

Mr. Gleadale introduced the stomach pump, and washed out the stomach very freely with warm water in the first place, and then with brandy and water, and finally introduced one drachm of compound spirit of ammonia, which was in a short time vomited, together with a quantity of food which had been taken in the early part of the day.

The coma now became more profound, the breathing stertorous and puffing, the skin cold, pulse imperceptible, and there were general convulsions.

He was removed to the hospital of the poorhouse, and about 11 P.M. was seen by the surgeon, Mr. Skinner, who found him in an extreme state of collapse, comatose, and very pale; skin cold; the pupils acting very, irregularly, sometimes much dilated, at others much contracted; breathing stertorous and puffing, and a frothy expectoration was expelled convulsively; sibilant rhonchus over the *whole* of the chest; pulse not more than 50, very feeble, and compressible; slight convulsive shiverings; the breath strongly impregnated with chloroform.

He was placed in bed, wrapped in blankets, and surrounded with tins of hot water. A large sinapism was applied to the chest, and a blister to the nape of the neck. He gradually recovered, and about two A.M., became sensible. A mixture of ammonia was ordered.

On the next morning, at 11 o'clock, he was complaining greatly of pain in the head; the conjunctivæ very much congested; the skin hot; respiration easy; pulse 90, soft; tongue red, and the papillæ raised. A slight sibilant rhonchus was detected over the whole extent of the chest, and the heart-sounds were roughened. He was ordered to take the powder of chalk, mercury, and rhubarb, and the saline mixture.

On Sunday much improved; the abnormal sound of lungs and heart gone.

On Monday he was much better, and on Tuesday he was discharged.

From the account given by him, it appeared that about 1 o'clock on Friday, he drank four ounces of chloroform, which he had taken from his master's surgery, (an ounce bottle of hydrocyanic acid was found in his pocket,) and from that time he had no recollection of anything until he found himself in the hospital of the poorhouse, not even of having gone into the barber's shop.

Correspondence.

ON THE STYPTIC POWERS OF MATICO, &c.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—On reading the remarks of Mr. Giraud, on the styptic qualities of matico, in connexion with uterine hæmorrhage, I find that he states that "his attention was first directed to the styptic powers of matico some years ago, by Mr. Hoare," &c. From this observation I conclude he has not seen the pamphlet of Dr. Jeffrey, of Liverpool, published some years since; and who was the first, I believe, to bring this powerful vegetable astringent prominently before the profession. If so, I would beg to direct Mr. Giraud's attention to Dr. Jeffrey's remarks; and I am sure he will find much useful and valuable suggestions from the perusal of his pamphlet. Very much depends upon a careful selection of the plant, as there are many spurious specimens offered for sale, as well as samples of a very inferior

quality. I have always found the *yellow green*, with a *fresh pungent smell*, the most powerful in its astringent effects, and that to be alone relied on. Many persons I know, have been frequently disappointed in the trial of this remedy from this circumstance, and on asking them the nature of the sample, have decribed it "as without much smell, and of a *dark green* colour."

I have employed matico to a considerable extent for some years, and can bear testimony with Dr. Jeffrey and Mr. Giraud to its invaluable assistance in *all* cases of hæmorrhage. I have used it very frequently, and I may say extensively, in passive hæmorrhagea, in cases of flooding after labour and miscarrying, also in hæmoptysis and epistaxis, in minor cases of obstinate and tedious bleeding from leech-bites, extraction of teeth, &c., in leucorrhœa, and chronic cases of gleet. In all these I have rarely seen it fail, and in many of them the effect has been almost instantaneous. I could cite many interesting cases, where matico has succeeded in excessive uterine hæmorrhage, after the trial of very many other powerful styptics. The method of administering it has been most frequently with me in the shape of infusion—an ounce or more to the pint; giving two or three table spoonfuls every one, two, or three hours, according to the severity of the case. In some cases of hæmoptysis, the patient has carried some leaves in his waistcoat pocket, and on perceiving the taste of blood in his mouth he took a pinch, and masticated it well, swallowing the expressed juice with the saliva. This plan has answered exceedingly well, and entirely checked an attack. To quote the words of the patient, "I never, Sir, should feel safe without some of this remedy in my pocket. The powder, *recently* pulverized, in doses of a scruple to half a drachm, I have found succeed where the ergot has failed in exciting uterine contraction; and from repeated trials of its efficacy in this respect, I feel convinced that many of my professional brethren would do well to try the powder of matico when they have failed to induce uterine effort from other remedies; and in cases of hæmorrhage I would rely most confidently upon the administration of this remedy. These remarks I have made with the same view as that of Mr. Giraud, and to add somewhat in assisting each other to arrest formidable attacks of hæmorrhage, which call forth all our promptitude and knowledge, producing no slight solicitude for our patients, and alike placing them in imminent peril. It is our duty to communicate, and place before our medical brethren the successful trial of any remedy which may assist them in the management of perplexing cases; and I am persuaded that if we were more unreserved and frank in this respect to one another we should do much benefit.

I am, Sir, yours faithfully,
PHILIP R. SLEEMAN.

Bristol, April 5, 1851.

THE APPRENTICESHIP SYSTEM.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—A communication in your last number respecting the present state of the medical profession, reminds me of a subject upon which I have frequently thought of addressing you, and some remarks made in the course of a review of a recent surgical work in the columns of the *Times*, renders a notice of the matter more urgent and necessary.

Your sexagenarian correspondent stands up boldly for the Apothecaries' Company, and in many of his remarks I most fully concur; as, for example, the good service which the company has done in advancing the education of surgeons, a service which ought to be appreciated more by the public than is the case, and the necessity which exists in the country districts of a medical man dispensing his own medicines, without charging for anything beyond his attendance.

I wish to say a few words upon a somewhat similar topic, viz: the apprenticeship system, decried by most of the London surgeons and the Council of the College, possibly because it is upheld by the Apothecaries' Company; and very strongly deprecated by Mr. Skey and his very flattering reviewer in that lengthy advertisement inserted some days ago in the *Times*.

Having had a good deal of experience in the education of young men for the profession, I beg to state my distinct conviction of the great advantages of an apprenticeship. I do not mean a servitude in a shop for five years, but an apprenticeship to a surgeon in the country or in town; if the former, and there is no recognized hospital or school sufficiently near, it should be with the understanding that the last two or three years be spent in attendance upon lectures, &c., at whatever school may be chosen, and this the Apothecaries' Company very liberally allow. I consider the advantages to be the following:—Being bound legally to serve his master, he is kept under his eye for a greater or less time, and has opportunities of learning many things of the greatest importance which hospital practice can never teach. There is a vast difference between hospital and private practice, and, in fact, the slight cases and operations which a young practitioner has to undertake, are seldom seen in the wards of a hospital. The master, moreover, would consider himself bound to teach his apprentice the *business* part of his profession, which is very necessary, and which a mere hospital pupil can never learn; the apprentice will have now and then to see some of his master's patients in his absence, and will be made do many things which it is very necessary to learn; he will have to assist at operations in private, and will learn to be a quiet and handy assistant; to sew up a body neatly at a private *post-mortem* examination; to bleed and cup expertly; and all the minutiæ which in the aggregate make up the practice of a surgeon just beginning his career. How few, in ordinary practice, except hospital surgeons, are required to perform capital operations; and yet these attract the greatest part of the attention of the students in the wards of the hospitals. Where, again, in a hospital is there any opportunity to watch the progress of ordinary cases of small pox or measles?

Having had myself the privilege of being an apprentice to a surgeon of high standing as a private practitioner, who did not dispense medicines nor require any menial servitude, but gave me private instruction, whilst I attended lectures and hospital practice, I can safely declare that I derived the greatest and most lasting advantages from the suggestions then received.

If the Apothecaries' Company resign their power of granting a license to practice to the hands of the College of Physicians, I hope that something tantamount to an apprenticeship will still be required; and I think that nothing short of the legal power of an indenture for three, four, or five years will answer the purpose.

In conclusion, I wish to express my opinion that the Council of the College of Surgeons are utterly ignorant of the condition of surgeons in the country, (I ignore the term "General Practitioner,") especially of those in large provincial towns, where, with the exception of attending midwifery cases, they are as much "*pure*" surgeons as the members of the Council themselves.

I remain, Sir, your obedient servant,

F.R.C.S.

ON THE COMMUNICATION FROM A "SEXAGENARIAN."

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—Without wishing to claim from yourself or your readers any credit for excessive sympathetic sensibility, I must beg permission to condole with you most sincerely with regard to your obligation to publish *such* "Sexagenarian Thoughts on the present state of the Profession." I would suggest, for your own sake, that you should cause all those who peruse the *Journal* to understand that the constitution of the Association *compels* you to insert whatever trash a member may be pleased to send, and that you are, therefore, not responsible for the fatuity of your correspondents. But, I would also suggest, that you should, in future, be debarred from the exercise of discretionary power, *only* on the condition that the *names* of those contributors who indulge in attacks against the entire diplomacy of surgery and medicine, should be appended or prefixed to the documents committed to the press. It is not my intention to specify the absurdities that prevail in the paper to which allusion has been made, because *one* edition of that paper is enough; nor is it my wish to be severe in remarking on the mental and moral infirmities of an aged man; my only object is seriously to propose that some measure should be adopted which may enable you to use your Editorial discrimination, and thereby reserve the pages of the periodical over which you preside for communications which bear the impress either of sanity, courtesy, or talent.

I remain Sir, yours faithfully,

One whose Reputation is not "European."

May 5, 1851.

[The communication alluded to is privately authenticated by the signature of one of the most respectable members of our Association, and however we may differ from him in many of his opinions, we think he had a right to expect the insertion of them in the *Journal*.—Ed. J.]

Medical Intelligence.

ANNIVERSARY MEETING, 1851.

We have authority from the Council to state that the next Anniversary Meeting of the Provincial Medical and Surgical Association will be held at Brighton, on Wednesday and Thursday, the 13th and 14th of August. Further particulars will appear in a future number.

BRISTOL MEDICAL SCHOOL.

The annual distribution of prizes took place at the Medical School, Old Park, Bristol, on Thursday morning, May 1. After an interesting and appropriate address to the students, Mr. Clark, Lecturer on Surgery, awarded the prizes to the following successful candidates:—For proficiency in the studies of the third academical year, a prize to Mr. G. L. Poole, and a certificate of honour to Mr. E. A. Hadow; for proficiency in the studies of the second year, the first prize to Mr. James A. Ellis, the second to Mr. W. H. Day, and a certificate of honour to Mr. H. H. Cox. These prizes are quite distinct from the clinical prizes annually awarded at the Bristol Royal Infirmary.

UNIVERSITY COLLEGE.

The annual distribution of prizes in the Faculty of Medicine in this Institution, took place on Saturday last; H. C. Robinson, Esq., in the absence of Sir James Graham, presided. The Dean of the Faculty, Mr. Graham, having read a report setting forth the position of the school during the preceding session, the chairman proceeded to distribute the prizes to the several competitors, and then concluded the proceedings by some observations suitable to the occasion. The following is a list of the gentlemen to whom the prizes were awarded:—*Chemistry:* Gold medal, J. Z. Lawrence; 1st silver, Wm. Roberts; 2nd silver, J. Footman. Certificates—4, J. C. Thorowgood; 5, Wm. Mushet; 6, S. J. Deck; 7, C. Follen; 8, W. Harriss; 9, P. J. Worsley. Birbeck Laboratory Students—Gold medal, P. Duffy; silver, James Smith. Certificates—3, H. Lawes; 4, A. W. Willis; 5, James Bell. —*Botany* (summer, 1850): Gold medal, J. W. de Tunzleman; silver, Thomas Hillier. Certificates—3, G. Buchanan; 4, John Dee; 5, W. B. Ramsbotham; 6, James Ekin; Wm. B. Mushet; 7, F. W. Sayer.—*Pathological Anatomy* (summer, 1850): Gold medal, Henry Thompson. Certificate—2, J. S. Gamgee.—*Anatomy and Physiology:* Gold medal, W. H. Flower. 1st silver, R. Grundy; 2nd silver, T. Hillier. Certificates—4, R. B. Smart; 5, St. John Edwards, A. Dupuy; 7, J. Gamgee, G. Buchanan; 9, W. Mushet; 10, D. D. Davis.—*Anatomy:* Gold medal, J. S. Gamgee. 1st silver, T. Hillier; 2nd silver, W. Roberts. Certificate—4, St. John Edwards; 5, J. Z. Lawrence; 6, W. Mushet; 7, A. Ingham; 8, A. Dupuy; 9, D. D. Davis—Junior class, silver medal, W. B. Rams-

botham. Certificate — 2, F. T. Bond; 3, H. W. Kiallmark; 4, S. J. Deck; 5, J. Merryweather; 6, J. E. Havard.—*Comparative Anatomy:* Gold medal, Jos. Lister.—*Medical Jurisprudence* (summer 1850): Prize, S. W. Sibley. Certificates—2, F. Marcin; 3, R. R. Banbury; 4, R. Bowman.—*Medicine:* Gold medal, S. W. Sibley. 1st silver, John Beddoe; 2nd silver, Jos. Lister. Certificates—4, W. G. Bacot; 5, A. Dupuy; 6, J. H. Bartleet, G. Buchanan; 8, S. Wright, A. Ingham; 10, W. H. Adam; 11, F. Martin; 12, A. Trousdale.—*Materia Medica* (summer, 1850): Gold medal, W. Roberts. 1st silver, J. W. De Tunzelmann; 2nd silver, J. Turle. Certificates—4, R. Grundy; 5, J. D. Weaver; 6, T. Hillier, J. M. E. Long.—*Surgery*: Gold medal, J. S. Gamgee; 1st silver, S. W. Sibley; 2nd silver, Joseph Lister. Certificates—4, J. C. Agnis; 5, S. Wright; 6, H. M. Greenhow; 7, A. Trousdale; 8, A. Dupuy, 9, Amos Ingham; 10, J. H. Bartlett.—*Midwifery* (summer, 1850): Gold medal, T. G. Fitzgerald; 1st silver, T. A. Bottomley; 2nd silver, W. P. Jones. Certificates—4, R. Grundy; 5, G. Buchanan; 6, J. Ekin; 7, J. Turle, F. W. Sayer; 8, J. M. E. Long; 9, A. Dupuy; 10, A. Trousdale; 11, R. Banbury; 12, A. Ingham; 13, E. A. Kirby.—*Dental Surgery:* Silver medal, John Caldcleugh.—Fellows' clinical medals: Summer term, 1850—Gold, T. G. Fitzgerald; silver, R. Bowman. Winter term, 1851—Gold, Wm. George Bacot.

COMPLIMENT TO MR. WAKLEY, M.P.

At a meeting of the Committee of the London and Provincial Medical Protection and Benevolent Society, held April 21st, Mr. Wakley, M.P., was unanimously elected an honorary member.

INFECTION FROM DRIED SKINS.

According to the Vienna journals, five persons have already died in Genoa of a disease communicated by infected dried skins imported into that city.

ROYAL COLLEGE OF SURGEONS.

The following gentlemen were admitted members on Friday, the 25th ultimo:—Henry Cracker, Launceston, Cornwall; Francis P. Cupiss, Diss, Norfolk; Joseph Thomas Holt Dunn, Whitstable, Kent; Thomas Henry Taylor, Hanbury, Gloucestershire; John Turle, Holloway; John Edward Tuson, Harley Street; Herbert John Walker, Sheffield, Yorkshire; Henry Osborn, Southampton.

The following gentlemen were also admitted members on Friday, the 2nd instant:—Francis Allday, Merthyr Tydvil, Glamorganshire; Joseph Byron Blackett, Green Street, Park Lane; Richard Carter, Toronto; James Balfour Cockburn, Guernsey; John George Darlington, Prees, Salop; William Jackson, Bolton-le-Sands, Lancashire; John Skinner, Exeter; William Bray Stephens, Plymouth; Charles Whatmough, Whitchurch, Salop.

SOCIETY OF APOTHECARIES.

Gentlemen admitted members on Thursday, April 24th, 1851:—Sydney Alder, Wakefield, Yorkshire; George Forster Burder, Clifton, Gloucestershire; John Page Burke, Royal Navy; Edmund Thomas Higgins, Gloucester; David Thomas Morris, Carmarthen; Cornelius Clark Rutherford, Doncaster; James Spark, Newcastle-under-Lyne; John Burchall Peren, South Petherton; John Williams, Cardiff.

Gentlemen admitted members on Thursday, May 1, 1851:—John Ansell Brown, London; George Bull, Lewes; Thomas Wilson Caird, Exeter; Peter Ambrose Cotterell, Birmingham; William Garrard, Clifton; Thomas Lowe, Edgbaston; Robert Leach, Martoch; Vincent Litchfield, Twickenham; Henry S. Leverton, Truro, Cornwall; Philip Vincent, Camborne, Cornwall; Henry John Wilkin.

THE NORTH WALES BRANCH.

The Annual Meeting of the North Wales Branch of the Provincial Medical and Surgical Association will be held at the Crown Inn, Denbigh, on Tuesday, the 17th day of June next. The chair will be taken at twelve o'clock, when the business of the meeting will immediately commence.

It is earnestly hoped that Members will attend the ensuing meeting, and contribute papers, cases, &c., for discussion; and it will facilitate the business of the day if due notice of such intentions be given to either Secretary.

As the Journal of the Association is open to receive any papers, and publish them in full, it is considered expedient that in the more extended communication a *vivâ voce* abstract only shall be received at the meeting.

Dinner on the table at four o'clock.

EDWARD WILLIAMS,
D. KENT JONES, } Hon. Secs.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

NOTICE TO MEMBERS.

Gentlemen who have not yet paid their subscriptions for the current year, or who are in arrears, are requested to forward the amount due either to the Secretary of the district in which they reside, or to the Treasurer or Secretary of the Association at Worcester.

The attention of Members is particularly requested to the following resolution, unanimously agreed to at the Anniversary Meeting, held at Hull on the 7th and 8th of August, 1850:—

"But if any Member's subscription remain unpaid twelve months after it shall become due, the *Medical Journal* and other publications of the Society, shall be withheld from such Member till his arrears be paid; and when any Member has been in arrears of subscription for the *space of three years*, application shall be made for the same by the General Secretary, and if the arrears be not paid in *three months* the name of that Member shall be omitted from the list of Subscribers; but the omission shall not be deemed, either in honour or equity, as releasing any gentleman from the subscription owing during his Membership."

JAMES P. SHEPPARD, Secretary.

TO CORRESPONDENTS.

Communications have been received from Dr. Radford, M., Dr. Tilt, Mr. Hewitt, Mr. Toynbee, Mr. Newson, and Mr. Lord.

ON THE

MANAGEMENT OF WOMEN AT, AND AFTER THE CESSATION OF, MENSTRUATION.

By E. J. TILT, M.D.,

Senior-Physician to the Paddington Free Dispensary for Diseases of Women and Children, and Physician to the Farringdon General Dispensary and Lying-in Charity.

Amidst the whole range of created beings it would be difficult to find one more worthy of the medical philosopher's deepest meditations than woman, in whom so many peculiar functions are grafted on those common to both sexes, and who thus admirably exemplifies the elasticity of that vital force which enables her constitution to bear up against the numerous derangements of the menstrual functions, against the complicated phenomena of childbearing and lactation, and then altogether to cast aside habits to which it has been wedded for so many years, in order to remodel the organism upon a new plan—a plan somewhat resembling that of man.

Having shown by what means the derangements of the menstrual function may be prevented, I have now to treat of the management of women during the last of the many revolutions by which their lives may be chequered, for it stands to reason that habits which have lasted more than thirty years, cannot be set aside without frequently entailing very serious ill health. Popular prejudice has termed *critical* the period of life characterized by this change, a term warranted by the experience of past ages, bearing the test of daily observation, and which gives peculiar importance to this inquiry. In asserting that this period of life is critical, I do not mean, however, to maintain with the older authors that more women than men die between the ages of 45 and 55, (for Duparcieux and Benoist de Chateauneuf have by statistical inquiry, proved the contrary to be the case,) but that the cessation of menstruation in women is followed by a greater amount of suffering and disease than is the lot of men during the corresponding portion of their career.

Admitting the cessation of menstruation to be a crisis in the life of women, it behoves us to know by what evils it may be attended and the remedies by which they may be alleviated or prevented; but I deem it necessary to preface my remarks by a pathological sketch of a subject, deriving additional importance from its intricacy and extreme obscurity; for in the little that authors say on the subject, they generally copy each other, giving no satisfactory account of the diseases to which women are peculiarly subject at this time, much less any well combined plan of treatment, only to be deduced from sound pathological views. No better idea can be given of the different modes of termination of the menstrual function and of the subsequent disorders thence entailed, than by analyzing 100 instances, wherein I have carefully noted the phenomena of its cesssation, and of the patient's subsequent state of health:—

With respect to the quantity of the menstrual flow, it terminated gradually in ... ... 35 per cent.
,, by a succession of floodings in 15 ,,
,, by a terminal flooding in ... 12 ,,
,, by alternations of a little and considerable flow in ... 7 ,,
,, by a sudden stoppage in ... 16 ,,

With respect to the periods of its occurrence the flow appeared at irregularly protracted intervals in ... ... 13 per cent.
,, irregularly contracted periods in ... ... 2 ,,

The gradual termination, then, is the most frequent, and as it is attended by a less disturbance of health, we should favour this mode of termination as far as lies in our power by the adoption of the remedies and regimen by-and-by to be recommended, and here I may remark, that the frequency of flooding, amounting to 27 per cent., seems to indicate bleeding as the best imitation of the process by which nature seeks to work out the remodelling of the female constitution. A terminal flooding has no doubt been sometimes taken for a miscarriage, and *vice versâ*, but in both cases as the same plan of treatment will be adopted, no danger can ensue. The sudden stoppage of the function claims more attention, for it occurs more frequently than is supposed at an early period of life; it may be then considered to be merely a temporary suppression and lead to the use of forcing medicines, and to serious mischief, of which an example will presently be given. This mode of cessation is not unfrequently mistaken for pregnancy in women married late in life or in those who have long ceased to bear children, a mistake the more easily made if cessation coincides with some amount of swelling of the abdomen and breasts, and other sympathetic disturbance, and of which time only shows the fallacy. The converse may occur, and pregnancy be mistaken for cessation, and the imprudent employment of purgatives or forcing medicines may bring on a miscarriage. It should never be forgotten that pregnancy happening towards the 50th year has been too often considered to be an ovarian tumour and treated as such, to the detriment of both mother and child.

I know of a very sad case wherein this happened to a lady who had been married twelve years, without family, and in whom menstruation suddenly ceased at 48. The lady believed herself to be pregnant, but the absence of previous conception, her advanced age, and her state of emaciation, led a very distinguished country practitioner to believe her to be afflicted with an ovarian tumour. The lady came to town to consult an eminent obstetric physician, and receiving the confirmation of the former opinion, used a bandage and applied mercurial ointment to the abdomen, but at the ninth month after she first supposed herself pregnant, she was delivered of a dead child. The Fabian policy is that best calculated to prevent such painful consequences: *cunctando restituere rem* should be the motto of the medical adviser.

After a long period of cessation the flow may reappear and return regularly for months or years, without,

however, indicating the return of procreative power. Amongst numerous instances related by authors, one of the most singular is that given by Meissner,* of a woman who first menstruated at 20, her first child was born at 47, and the last of seven other children at 60. Menstruation ceased and reappeared at 75, continuing until 98, then stopped for five years, again to return at the advanced age of 104, when (in 1812) she was still alive. Evidently confounding this occurrence with cases of flooding caused by organic uterine disease, Meissner and others attribute a host of evils to this reappearance of the periodic flow, whereas it is perfectly harmless, and should rather be considered as a salutary effort of nature to prevent serious disease in certain constitutions. All women should therefore be aware of the possibility of this occurrence, so that they may not forcibly repress the flow; but they should likewise be aware, that in such cases it is necessary for the medical man to make a very careful investigation, in order to ascertain whether the loss of blood does not depend on cancer of the womb, or on some organic disease of this organ, susceptible of being cured.

Case.—F. Webb applied for relief at the Paddington Free Dispensary, July, 1, 1850. She was 46 years of age, of sanguine temperament, and of middle stature. She was a washerwoman by occupation. First menstruating at 17, she continued regularly to do so, and that very abundantly, for seven days every month. She married at 21, and had nine children, the last at 44. The last was a bad labour, and she has suffered ever since from pain in the back. Two months previous to her admission, instead of menstruating as usual, she had a *show* every day; a fortnight before she applied for relief she had a sanious discharge, and on the day of her admission she had suddenly lost about a pint of blood. I looked on these phenomena as indicating cessation. A few days after this she was taken with intense flooding, and in the space of sixteen hours she had lost from three to four quarts of blood. Having been called to attend a patient some miles from town, Mr. —— kindly visited her during my absence, and on my return I found her reduced to the greatest state of debility. There was a very weak pulse, fainting and jactitation. As the flooding still continued, I passed a lump of ice up the vagina, ordering it to be replaced by another as soon as the first was melted. I also applied ice to the hypogastric region, and a bandage as to a woman recently confined. The flooding soon stopped, and was followed by a muco-sanious discharge. A digital examination made during the flooding, convinced me that there was serious organic disease of the womb, and from the irregularity of the internal surface of the neck of the womb, into which the finger easily plunged, and from the hardness of the tissues I considered the disease to be cancer, but on making a specular examination a fortnight after, I found the orifice of the neck of the womb surrounded by lobules about the size of a large pea, and the inner surface of its neck highly vascular, in some portions ulcerated, and the whole of the organ much engorged. Being convinced from ocular inspection that the disease was of a purely inflammatory nature, I adopted the treatment which I have found the most useful in such cases. I touched the surface with the solid nitrate of silver, and a week after I gently applied the Potassa Fusa c Calce to the same surface, when the swelling diminished, and the structures put on a healthy aspect. Six subsequent applications of nitrate of silver cured one of the most frightful examples of uterine disease I have ever met with. The patient soon recovered her strength, but menstruation remained irregular. Dec. 12, she came to the dispensary because the menstrual flow had lately remained on her for a fortnight, and had been very profuse. On examination, the womb, however, was found perfectly sound; and so it was a few days ago when I last saw the patient.

Few cases can be more instructive than the above. If the symptoms of uterine disease following the last confinement had been attended to, the patient would not have been placed at death's door by flooding. By means of the speculum alone was it possible to ascertain that the disease was not cancer but inflammation. It was only by the use of the same instrument that I was also able to cure so serious a disease in a few weeks, and to restore the patient to the laborious duties on which she depends for the maintenance of her children.

Few departments of pathology have given rise to so much confusion as that which treats of the diseases of women at the critical time; while some, with Dewees and Meissner, deny that women are then more liable to disease; others, with Gardanne,* seem to consider, as diseases of the critical time, all those which may afflict a woman after she has passed her 50th year, a position evidently incorrect, for many diseases attack women at that period not because they are women, but on account of their being advanced in years; such as diseases of the heart or the larger vessels, and softening of the brain, which are diseases of old age.

Diseases of the critical time may be divided,—1st, into those which are of very frequent occurrence, and may be foreseen; 2nd, those which seldom occur cannot be calculated, and can only be explained by the well-known fact, that the impetus of morbid action tells most forcibly on the weakest organ, for we must be cautious not to consider as disease of the critical time that which would have been long before discovered if looked for, as in the case just related of Frances Webb. However, those diseases which, although previously developed, proceed with increased activity after that time, may fairly be considered as the result of an alteration in the constitution, brought about by the change of life.

1st.—Having carefully noted the morbid phenomena which occurred at cessation in 100 women, it seems to me that some of the most frequent symptoms may be referred to the cerebro-spinal system, and others to the ganglionic system of nerves.

* Almanach für Aerzteund Nichtarzte veuf das Jahy, 117. Rostock und Leipzig.

* Avis aux femmes qui entrent daus l'age critique. Paris. 1816.

Cerebral Symptoms.

Headache, sick-headache, hysteria, and pseudo-narcotism existed in	64	per cent.
They were augmented in ...	36	,,
,, remained the same in ...	18	,,
,, were less in	10	,,
,, did not exist in ...	36	,,
	100	

Thus, when the habitual derivation from the sanguineous mass is no longer regularly performed every month, the cerebral functions become impaired in 64 per cent. In addition to other head symptoms, the patients complain, to a varying amount, of drowsiness, of a heavy stupid headache, of vertigo, and have sometimes the physiognomy and the tottering gait of intoxication, and many other peculiarities that space will not permit me to enumerate, and which have led me to introduce the term *pseudo-narcotism*, to express a state of the nervous functions which, although noticed by Ashwell, Gardanne, Meissner, and others, has never received sufficient consideration from the profession, being only partially alluded to by those who have written on hysteria and cephalagia, and which will never be sufficiently studied until, distinguished by a *name*, it receives a local habitation amongst recorded facts.

Spinal Symptoms.

Spinal or dorsal pains existed in ...	70	per cent.
They were augmented in ...	46	,,
,, the same in ...	17	,,
,, less in	7	,,
,, did not exist in	30	,,
	100	
Hypogastric pains of a bearing down character, referred by women to the womb and ovaries, existed in...	51	per cent.
They were augmented in ...	30	,,
,, the same in	12	,,
,, less in	9	,,
There were none in	49	,,
	100	

Thus the nervous influence which used to direct a regular discharge is still in force, a fact proved by the persistence of the spinal pains in 70, and of the hypogastric in 51 per cent. They sometimes appear regularly every month, not unfrequently determining leucorrhœa and diarrhœa in some severe cases.

Ganglionic Symptoms.

Am I wrong in referring the following symptoms more particularly to that nervous system, the filaments of which, like a web, envelop each arterial vessel in their inextricable mazes?

Faintness, exhaustion and sinking, (often referred to the epigastric region,) existed in	26	per cent.
Heats and flushes were noticed in	38	,,
Perspirations in	30	,,
Sweats in	16	,,

These symptoms, little dwelt on by pathologists, derive great importance from their frequency, and also from the insight they afford into the means by which nature relieves the system of the fluids that are no longer discharged every month; for when the periodical secretions from the uterine and the intestinal surfaces are checked, it seems as if the mass of fluids were thrown on the extensive surface of the skin, which is so frequently found to stand in antagonistic relation to these surfaces; thence arise the heats, the flushes, the gentle perspirations, by which, in the generality of cases, further mischief is prevented. It is not surprising that it should be so, for long ago Sanctorius established that—"Insensible perspiration alone, discharges much more than all the sensible evacuations put together."—Sec. I., *Aph.* iv.

It will be remarked, however, that in 16 per cent. the cutaneous exhalation by its amount became itself a disease, and without relieving the patients, as well as the more moderate exhalation, which would not be understood were it not for the uncontradicted remarks of the same accurate observer:—"That perspiration, which is beneficial and most clears the body of superflous matter, is not what goes off with sweat, but that insensible steam or vapour which in winter time exhales to about the quantity of 50 ounces in the space of one natural day."—Sec. I., *Aph.* xxi. "Sweat is always from some violent cause, and as such (as Static experiments demonstrate) it hinders the insensible exhalation of the digested perspirable matter."—Sec. V., *Aph.* iii.

The drenching perspirations seldom last very long, but the heats, the flushes, the gentle perspirations, often continue to appear several times a day ten or sixteen years after the cessation of menstruation. The salutary effects to be derived from this agency, the value of which has been too little understood, are well exemplified by the following singular case:—

Jane Ayre, aged 40, with dark hair, grey eyes, of small stature, nervous constitution, and slender make, was admitted at the Farringdon Dispensary on February 8th last. After having frequently suffered for two years with violent headache and giddiness, she menstruated for the first time between 15 and 16; was regular from the first, and continued so and very abundantly during seven days every month. She married at 16, became pregnant immediately, had seven children, the last in her 26th year; was always poorly until she quickened, and in three pregnancies she menstruated regularly up to the period of parturition. Last summer she was treated, at the Royal Free Hospital, for rheumatic fever, and after having been confined to her bed for three weeks, she returned to her domestic duties, merely complaining of some slight pain, extending from the left hip to the great toe. Menstruation proceeded regularly during the patient's stay at the hospital, appeared four times after her return home, and then stopped; a circumstance which made her believe she was pregnant. The patient complained of an intolerable increase of the pain in the left lower limb, and on examination I found that pressure on the spine did not

increase or cause the pain. To all appearances the left limb was as sound as the right, and the pain was said to arise from before the great trochanter, and to gain the back of the limb, following the course of the bones to the toes. The patient was not strong; the pulse weak; the urine clear, and of the usual colour. I ordered a blister to the spot which was the most painful, pills of compound colocynth, and a sedative mixture. The blister did not relieve the excruciating pain. Turpentine embrocations were added, the other measures continued, and the blister repeated, without the least benefit.

March 8th.—The patient said that she no longer thought herself pregnant, and she suggested that her pains might have been caused by the sudden cessation of menstruation, five months back. On learning that she had lately had flushes and night perspirations that she had never had before, I adopted the patient's view of her case, and ordered, as an emetic, Ipecac, scr. j; Ant. Pot. Tart., gr. j. I continued the mixture and pills, and ordered a teaspoonful of flower of sulphur to be taken on going to bed at night, in milk.

15th.—The heats and perspirations had increased; the pains had much abated. I ordered another emetic, and continued the other measures.

29th.—The pain is very trifling, and the heats, flushes, and perspirations are more frequent, coming on not only on exertion, but in bed, at night and in the morning.

April 6th.—I ordered the following powder:—Sul. Sublim, oz. ij.; Sodæ Sesquicarb, dr. ij.; Pulv. Ipecac., gr. x., a teaspoonful at bed-time.

19th.—The patient is much better; she has no continued pain, but feels a *sensation* as when one has suffered from toothache and another attack is coming on. Two or three times a week the pain shoots down the limb and lasts about a minute. The heats, flushes, and gentle perspirations continue. It is now more than seven months since she menstruated.

Jane Ayre has not suffered in any other way from the cessation of menstruation; and when we consider that she was subject to a copious discharge every month, we can understand that she should suffer from a sudden cessation; and, further, when we remember that in her constitution there was a great predominance of the nervous system, it is not surprising that this system bore the brunt of the sudden shock, particularly that portion of it which was predisposed to illness by the previous attack of rheumatism.

Amongst other diseases occurring frequently at the cessation of menstruation, I must first notice those which implicate that organ which has attained the last stage of its functional activity—the womb.

I have already shown that flooding occurred, under various circumstances, in 27 per cent. An increased mucous secretion from the generative intestine is also a very frequent circumstance, for I found

Leucorrhœa existed in	58	per cent.
Was augmented in	44	"
" stationary in	8	"
" diminished in	6	"
Inflammatory diseases of the womb occurred in	4	"

It has happened that I have not met with a single case of cancer; but it is too well known that women are at the change of life more than ever, and more than man, liable to that terrible infliction.

It is not difficult to understand that the local plethora should often seek to find a vent on a surface intimately associated with the uterine; and accordingly it was found that

Hæmorrhoids existed to various extent in	20	per cent.
They appeared for the first time after cessation in	12	"
They did not bleed in	4	"
" were bleeding in	8	"
" were considerably increased after cessation in	4	"
" remained the same in	2	"
" diminished at cessation in ...	2	"
Intestinal hæmorrhage existed in ...	2	"

In some cases, either because the intestinal plethora was less considerable, or because the nervous impulse was less, there was an increased mucous discharge from the intestines.

Diarrhœa existed in	12	per cent.
It was irregular in	8	"
" regular by coming on every month in	4	"

Such is the long list of infirmities which seem to me evidently dependent on the change; but to prevent an erroneous impression respecting the dangers of this crisis, we should observe that many of these diseases existed in the same patient, and that their repeated occurrence was spread over a space of time varying from one to ten years. The perusal of this list is sufficient to convince any medical man that the unavoidable diseases of cessation are more annoying than dangerous, and that the most frequent have attracted the least attention, while undue consideration has been given to those of less frequent occurrence.

2nd. With regard to the numerous other diseases which have been set down by some authors as those of cessation, I can only repeat that their appearance depends on some constitutional peculiarity, and is governed by no other law except that which directs the impetus of any morbid action to the weakest organ. Frequently, however, this explanation will not hold good. Thus, a lady consulted me very lately. For the last ten years since cessation she had been more or less troubled with water-brash, although previously to that epoch she had never even suffered from indigestion. The following is a good illustration of the same fact:—

Case.—Maria Baker, aged 50, first menstruated between her 18th and 19th years, with little previous disturbance, and continued regular until 20 years of age, when she married. She has had nine children, the last when 44 years of age. At 48 she had several floodings, but without much increase of pains in the head. The catamenia ceased at 49; this was followed by no disturbance of health, except by a severe attack of nettle-rash, three months after, on the chest and body, which disappeared on the proper medicine

being administered; twice, however, it has recurred at irregular periods, and on the 28th of March last she applied for relief at the Farringdon Dispensary for a fourth well-marked attack of the disease on the lower part of the body and thighs.

As this patient had never before had the slightest rash, and as this nettle rash has appeared four times in the year which has elapsed since cessation, I believe it to have been caused by this crisis, as in the case cited by Tissot, of erysipelas of the face occurring fifteen times during the two first years after cessation, less frequently during the two next years, and only once during the fifth year. I do not mention these cases to prove that skin diseases frequently happen at this time, (for they only form six per cent. of mine,) but merely to give an example of what I understand by diseases of the critical time.

It will be easy for any one to fill up the deficiencies of this paper, for I have only been able to sketch broadly the principal outlines of an interesting subject. My object has been to attempt to elucidate from more careful investigations some general rules of treatment, and the conclusion to which I have been led is—*that the regulation of the circulating and of the nervous systems* is the guiding principle of action, to be constantly kept in mind to promote the cure of, or at least to guard against, the diseases brought on by the change of life, and this can only be effected by combining a judicious regimen with various therapeutical means.

Regimen.

What has already been said upon this subject, applies with equal force to women who have arrived at the turning point of life; but to derive benefit from the best advice, it is necessary to believe in the evils it is intended to avert. Women should, therefore, be impressed with the conviction of the dangers that await them, while, at the same time, they should be convinced that those which they really have to fear depend upon causes almost entirely under their own control. Unfortunately, it too often happens that women are not made aware of the necessity of taking precautions till the function has entirely ceased; whereas these should be taken as soon as nature shows its intention to effect a change by repeated irregularities in the *amount* of the accustomed discharge, as well as in the time of its appearance.

For practical purposes, women at the change of life may be divided into—

1st.—Those who are endowed with a strong constitution, who are, generally speaking, of a sanguine temperament.

2nd.—Those who are of a weak constitution, either on account of their having been gifted with too great a predominance of the lymphatic or of the nervous temperament, or from long-continued ill health.

In general, those who are of a lymphatic temperament, suffer least at the change of life, and they often become more sanguine, muscular, and subsequently robust.

The nervous, on the contrary, are often liable to repeated floodings, and suffer considerably from the different varieties of head symptoms which I have enumerated. The sanguine are those on whom the change of life tells most forcibly, and this may necessitate for many years the most prudent use of many things previously enjoyed with perfect impunity. Descending from generalities into practical details, I shall observe, that while the lymphatic and the nervous need make no change in their mode of living, the sanguine—those who are of a full habit—would do well to put themselves on Lenten fare, to dine off the lighter kinds of fish two or three times a week; and it is better to make the principal meal at the fashionable lunch hour of two o'clock, in order that the last meal may be a very light one, which can well be managed, even if the duties of society should require a lady's presence at a seven o'clock dinner table. The strongly constituted, as well as the weak, often suffer from most annoying sensations of internal sinking, exhaustion, and faintness; but it is dangerous to seek to relieve such feelings with wine, cordials, and spirits, by which a temporary support can only be obtained at the expense of an increase in the faintness, flushes, perspirations, and nervous symptoms. Is it necessary to mention that these symptoms will be increased by the frequenting of balls, routs, operas, &c., when, in addition to the numerous stimuli to be encountered, hot and impure air must be breathed? But if the late-hour exercises of civilized life are dangerous to all, particularly to the sanguine; gentle, regular, and long-continued exercise in the cool of the day is equally beneficial. It prevents the congestion of internal organs by diverting the blood to the muscles and the skin, the secretions of which vast surface are thus greatly increased; and it also has an incontestable good effect on the nervous functions, exhausting those redundant energies, which, however little understood, when unemployed, produce the fidgets, nervousness, temper, hysteria—a sliding scale which imperatively leads to more serious mental disorders. My observations apply more particularly to walking exercise; driving in an open carriage is likewise good, but horse exercise should be left off when menstruation is ceasing, for its utility in favouring menstruation sufficiently points to the discontinuance of the practice at cessation.

It must not be forgotten that sleep is verily "great nature's second course," and therefore should not be too freely indulged in by those who are of a full habit—they should rise early; the nervous, on the contrary, may be encouraged to take as much sleep as nature will give them, as it is for them the best restorative, and an anti-spasmodic of heroic force.

One word respecting dress, although I feel that it is one of those subjects of which the poet says that—

"Fools rush in where angels fear to tread."

At the cessation of menstruation the vicarious functions of the skin are so important as to require its being covered as much as possible, even if good sense did not whisper the impossibility of competing with complexions animated by younger blood. Tight lacing, hurtful at all times, is perhaps most so at the cessation of menstrua-

tion, as it favours the congestion of internal organs, but I do not deny the necessity of supporting, by well-contrived stays, those organs which have lost the resiliency of youth.

Another very important observance to all is the proper cultivation of the healthiness of the skin. We have seen how frequently this vast surface is vicariously entrusted with most of the labour which the womb now refuses to accomplish, and thus we obtain an insight into the utility of frequent ablutions at this period of life. By ablutions I do not mean washing with a sponge or towel, but real ablution in a bath. It is surprising of how much effete matter a skin, which even looks clean, is deprived, by the body being allowed to soak in hot water for half an hour or more. The habitual use of the bath was found so useful by the Greeks and Romans, and is now in such constant use in neighbouring countries enjoying a climate similar to our own, that it is surprising that so few amongst our women, of whatever grade of society, have recourse to bathing, except, perhaps, for a few weeks of the year at the sea-side. The practice of bathing is not only to be advocated on the plea of cleanliness, and facilitating the removal of the excretions from the body, but it has a direct sedative influence on the nervous system; it seems to absorb that morbid irritability arising from an undue development of the mind at the expense of the body, and leaves a feeling of comfort and repose not wholly to be attributed to the consciousness of being clean. The bath should be used at least every week by those who are at the change of life, and more often by those who suffer much from profuse perspirations. The water should be sufficiently warm to impart a grateful sensation—from 94° to 98°,—the patient should remain in it half an hour, or an hour, and the head can be sponged with cold water, if the first impression of the bath is to cause headache. When employed while the function has not ceased, the time of the flow should not be chosen to take the bath, for it might produce flooding.

What I have said respecting the management of the skin reminds me that it may be usefully influenced by friction, moderately and gently performed by a practised hand. While watching in eastern countries the long-continued and gentle rubbing of the limbs and feet of the rich by their attendants, I could not help thinking that the process might perhaps be less due to the mechanical friction than to some kind of influence of friction on the nervous expansions, with which the skin is so abundantly supplied. Rubbing until the skin glows, or the actual grooming of the human skin, may be very useful to improve the health of scrofulous children or chlorotic girls, but it is not adapted for women at this late period of life.

My former reflections on the moral and mental management of women are now equally applicable. The full conviction that age has stamped them with its irrevocable seal may indeed cast a momentary gloom over the imagination, but in a well-trained mind it must soon be dispelled, if not by the consciousness of a well-performed career, at least by the knowledge that this epoch proclaims an immunity from the perils of child-bearing and the tedious annoyances of a monthly restraint; that it may even promise them a length of life and a strength of constitution superior in general to that of the opposite sex similarly advanced in years. This period of freedom has been employed by many eminent women in literary pursuits, or in governing with great discretion that circle of society—limited or extensive—in which they have been placed; becoming the guides, the supports, and the mainstays of both sexes in the difficulties of life. It is well that those who have suffered much at every month should know that there is every reason to believe that their "constitution will then at last settle" into permanent good health.

Solomon asserted "there is a time for all things,"* and he would have added, particularly for marriage, if he had found it necessary to give us the benefit of his vast experience in the management of a sex he understood so well. Early marriages generally ruin a woman's constitution, and late marriages—those which take place towards the critical time—are often attended by consequences which justify the ridicule thrown over such alliances. *Ridendo castigat mores.* Widows towards the evening of life should not be tempted by the happiness of a former union to risk another, and should seek the less tumultuous satisfaction to be derived from the affection of children, and their advancement in the battle-field of life. Those who have attained their sunset without having been granted the anxious yet desirable vicissitudes of wedded life should thenceforth be content to remain in single blessedness: and surely the most destitute of relatives—the most unfortunate in friendships, can still find in the various forms of unmerited affliction which fill our country cottages or the hovels of our populous cities that whereon to expend a warmth of feeling—an energy of self-sacrifice, which the sophisticated state of society has not permitted to flow into their natural and more grateful channels.

Much less should any vain and desperate attempts be made to stay the inexorable hand of time by protracting the re-appearance of the sign of womanhood. The use (the abuse of) emmenagogues or forcing medicines at this period of life would be a subject alike interesting and painful to the medical moralist; but it is better to drop the curtain on many of the wounds to which we are often asked to admister relief, and I shall close the subject by a case which exemplifies what has been done.

Some years ago I was consulted by Mrs. ———, aged 48, with dark hair and eyes. First menstruating at 14, she had continued regularly to do so, and without much pain, during all her life. When about 25 she formed an attachment in every way suitable, but family circumstances prevented an union from taking place. This attachment was kept up with a perseverance that

* Ecclesiastes, chap. III., verse 1, "There is a time to every purpose." Verse 17; chap. VIII., verse 6; chap. III., verse 2, "A time to be born, and a time to die; a time to plant, and a time to pluck up that which is planted," &c.

would grace a novel, till fortune smiled upon them, and in her 45th year the lady married. Menstruation had proceeded regularly as to time, quantity, and symptoms, up to the period of marriage, but subsequently it never re-appeared. As this sudden cessation coincided with gastric symptoms, a tympanitic tension of the abdomen, and, above all, a great anxiety for children, the patient was considered pregnant, and carefully watched for many months. When the illusion was destroyed, the lady became disconsolate; and punctilious in her notions respecting honour, she brooded over the possibility of her husband supposing that the courses had already stopped previous to her marriage. She consulted me, and was ready to submit to any operation. After a minute investigation of the case, I intimated my conviction that she was in perfect health, and that menstruation had ceased in an unusual manner. The patient would, I think, have given all she possessed to have been able to obtain another interpretation to the absence of menstruation, and left me unsatisfied. About a year after, I was asked to see the same patient, and learned, that having consulted some one else, she had taken steel, purgatives, and strong medicines, port wine and meat twice a day, without effect for the first few months, but then she had a terrific flooding. She had subsequently had continued sanguinoid discharge for several months, which had induced a state of great emaciation, and the usual symptoms of uterine disease. On examination I found a general painful swelling of the womb, with granulations on both lips. Leeches to the seat of the disorder, and the repeated application of nitrate of silver, cured these local diseases, but her nervous system never recovered the effect of an ill-advised treatment, and to use the mildest term, she is at all times in a highly hysterical state.

This sad case, and the foregoing hints, will suggest to a medical man the advice necessary to be given to women passing through this critical epoch, and with this I feel inclined to conclude a subject already perhaps irksome to many, but as women at that time are affected with so many indispositions and diseases pertinacious, complicated, and shrouded in such misty confusion, I shall redeem a former pledge by adverting, in a concluding paper, to the treatment of those diseases, and for the sake of brevity I shall embody what I have to say under the heads—bloodletting, sedatives, purgatives, and local treatment.

8, York Street, Portman Square.

CASES IN MIDWIFERY.

By THOMAS RADFORD, M.D., F.R.C.P., Edin., &c., &c., &c.

Consulting Physician to the Manchester and Salford Lying-in Hospital.

The relation of cases in every department of medicine is highly important to the profession, and in none is it more so than in midwifery. It is, however, the duty of the practitioner truthfully to register his unsuccessful cases, as well as those which terminate successfully; any other course is culpable. The value of cases does not consist in a selection from the case book of those only which tend to the greatest *eclât* of the writer; this may feed his vanity, but it deceives the profession. If a full and candid statement is made of all, then the aggregate will furnish data from which correct statistical tables can be drawn out. Every medical practitioner ought to have sufficient moral courage to stand against both professional and popular opinion, and be guided by a higher principle in the discharge of his duty. It is no less desirable that Christian charity should abound in us as a body, which would lead, and indeed make each and all of us always ready to allow for the want of success in others.

Case I.

Cæsarean Section.—*(Unsuccessful.)*

On Tuesday evening, Feb. 21, 1841, Mr. Dunn, surgeon, of Manchester, and Mr. Goolden, of Stockport, called upon me to request my opinion on the case of Mary Forrest, who resided at Stockport. She was the patient of the latter named gentleman, from whom I learned the following particulars:—He had visited her at 1 o'clock, P.M., the day before (Monday.) She was at the full period of gestation, and had violent and regular pains in the back. Mr. Goolden made a vaginal examination, and found the pelvis very much distorted; he thought she could not be delivered unless by the Cæsarean section. A grain of opium was ordered to be taken every two or three hours, until the pains abated, which happened after six doses had been taken. When Mr. Goolden visited her on Tuesday morning he found her nearly free from pain. Her bowels being constipated, some pills, composed of aloes and calomel, were prescribed. He again examined her per vaginam, and concluded that her delivery was impossible, except by the means already stated. He further said on the evening of this day, (Tuesday,) when at my house, that she was now entirely free from pain, and on inquiry said he did not think that labour had commenced. The object of his coming over to Manchester was to request me to visit the patient the following day, and examine the pelvis, so that clear and definite views might be had, and what course should be adopted when labour came on. On Wednesday I accompanied Mr. Dunn to Stockport. We found Mary Forrest in bed, and so helpless as to be unable to turn herself. Her countenance was short and inexpressive; her lips thick; her eyes blue; on the cornea of the right eye there was a considerable opacity, the result of an injury from having been struck by a shuttle. She had been employed as a power-loom weaver in a cotton factory. Her age was 38 years. This was her third pregnancy, though an unmarried woman. Her first labour, which was natural, happened nineteen years since, and the child was a boy. About eighteen months before her present labour she became pregnant a second time, and aborted at the end of two months. She had suffered during the last five or six years violent rheu-

matic pains, but otherwise her health had been good until within the last few months. Her stature had become considerably less, and her legs and thighs were very œdematous. She said she felt the movements of the infant, which on first placing my hand on the abdomen, I thought I perceived; but keeping it steadily applied, I soon found that it was only slight contraction of the uterus. The stethoscope was used, but gave us no evidence of its being alive. The abdominal parietes were extremely thin, and felt very flabby. The uterus projected very much forward, and lay over the symphysis pubis to such a degree, that when the patient was placed in a sitting position in bed its anterior surface rested on her thighs. Her breech was gibbous, and her thighs approximated considerably more than natural. The discharge from the vagina was of a dark colour, and had a putrid smell. Her constitutional condition was very bad; pulse 140; tongue furred; great thirst; continual vomiting; great abdominal tenderness and tension; bowels not moved for two days.

By a vaginal examination the pelvis was found to be considerably distorted, the outlet was so much diminished as to render it difficult to pass the hand, in order to ascertain as precisely as possible the measurement of its several parts. The arch of the pubes was nearly destroyed by the near approximation of the rami of the ischia and pubes, there being only a narrow slit which just admitted the point of the finger. Between the tuberosities of the ischia I could barely place three fingers. The coccyx was considerably incurvated upwards and forwards. The brim was tripartite in figure, or composed of three divisions. This altered shape was produced by the upper portion of the sacrum, and the last lumbar vertebræ standing so very much forwards and downwards, inclining a little more to the right side, and by the body of the ossa pubis and ischii being forced backwards and inwards, and the rami and symphysis pubis jutting forwards. On the right side I could just place the point of the index finger, and on the left I could pass two fingers, one lying partially over the other. Neither the presentation of the child or the os uteri could be felt.

Although my attendance was specially requested to explore the pelvis in anticipation of labour, and conclude on the measures which must be adopted when it supervened, we were compelled now to decide on her delivery, as she was, and had been, in labour since Monday, when the membranes must have ruptured, as I ascertained she had a dribbling watery discharge afterwards. We unanimously agreed that she could only be delivered by the Cæsarean section. When we apprized this poor creature of our decision, she readily consented to submit to any plan we considered necessary. An enema was administered, but it did not act. The catheter was passed, and about an ounce of urine withdrawn; afterwards I placed the hand on the abdomen, and found still a fluctuating tumour, which induced me to pass a longer catheter, and by a careful manipulation it was carried higher, and succeeded in further removing a considerable quantity of urine.

In the first place we arranged the duty which each gentleman had to perform. Mr. Cheetham and Mr. Pigott joined us to witness the operation. I commenced to make the incision a little above the umbilicus on the left side of the linea alba, and extended it downwards towards the pubes, so as to be about six inches in length. In consequence of the very attenuated state of the abdominal parietes the uterus was at once exposed, and its tissue partially cut. It was necessary to raise the deflected uterus upwards before the external incision was made. About a pint of water with a large portion of intestine now escaped. This portion of bowel, which had been dangerously exposed to be wounded, being effectively drawn aside by Mr. Dunn, I fully divided the uterus in the line of the wound first made into it. The placenta was now exposed, the greater part of which lay more towards the right side of the incision, and maintained its adherence, whilst that on the left (the smaller division) was separated by the contraction of the uterus. Mr. Dunn immediately passed his right hand in search for the feet of the infant, and his left along the body to guard its neck from being spasmodically seized during its abstraction (a caution given to him by me) having in a previous case met with this disaster. Having gained firm hold of the feet of the infant, he very cautiously and expeditiously drew the body forth, until the neck came to pass, which was then firmly grasped by the uterus, and the head thereby detained. The womb had an appearance as if it was indented, and strongly reminded us of its condition in hour-glass contraction. The difficulty at last overcome, the infant (dead and partially putrid) was completely removed. The adherent portion of placenta was detached, and wholly extracted. Not more than a few ounces of blood were lost. The intestines were much distended with air, and were difficult to keep in position during the operation, and could not be replaced or retained after it until the wound was contracted by sutures. Their peritoneal coat was highly inflamed. The edges of the wound were brought together by interrupted sutures, and maintained by straps of adhesive plaster, and supported by a bandage placed round the patient. She bore the operation with great fortitude, and indeed scarcely made a complaint during its performance. Afterwards she said she had not suffered so much pain as she had felt from some of the unavailing parturient pains. She now expressed herself as being very comfortable.

Nine o'clock P.M.—Considerably worse; pulse 140; tongue furred; great thirst; vomits continually; surface cool; countenance anxious; great tenderness of the belly; clyster not returned; had no sleep; a little urine passed; ordered to take Morph. Acet., gr. j.

Thursday 23rd.—Two o'clock A.M.—Mr. Goolden visited her; pulse 160; vomiting unabated; matter rejected of a dark colour; skin rather warmer; breathing quick; belly very tender; had no sleep; bowels still constipated. Ordered Morph. Acet., gr. j.

Nine o'clock A.M.—Mr. Goolden and Mr. Cheetham reported that she continued to vomit the same fluid; skin warmer; pulse less frequent and countenance less

anxious; bowels moved; passed urine; lochial discharge; abdomen tense and sore. To take Morph. Acet., gr. j., and saline effervescing mixture.

Half-past one o'clock P.M.—Mr. Goolden was urgently summoned; it was stated she was dying; he found her very drowsy or lethargic; had great difficulty to rouse her; pulse 140; countenance flushed and rather bluish in colour; no vomiting; abdomen distended.

Two o'clock P.M.—Present — Dr. Radford, Mr. Goolden, Mr. Dunn, and Mr. Piggott. She still continues very drowsy; pulse 140 and very tremulous; skin bedewed with a cold perspiration; her countenance is sunken, and her cheeks are of a purplish colour; her breathing very hurried, with mucous râle; does not vomit; belly tympanitic; bowels not moved. Ordered an enema with Sp. Terebinth., &c.

The symptoms continued to grow worse until seven o'clock (*vespere*), when she expired, having lived about twenty-seven hours after the operation.

Body examined twenty hours after death, by Mr. Dunn and Mr. Gaskell, in the presence of Dr. Radford, Mr. Goolden, Mr. Piggott, and Mr. H. Winterbottom. General tumefaction of the abdomen; its parietes being extremely thin. The edges of the external wound were nearly altogether adherent; adhesion of the peritoneal surfaces of the intestines and that of the abdominal parietes. On breaking through these adhesions, about a pint of bloody serum was discharged. The convolutions of the bowels were firmly united, and effused lymph was seen on their surfaces. The colon adhered to the uterus. We were particularly struck by the very remarkable pallidity of the tissue of the intestines when compared with their highly injected vascular state seen during the operation. The uterus stood obliquely; the wound in this organ was three and a half inches long; its edges were flabby and gaping; the os was very patulous and its lips ragged and gangrenous. The lower portion of the cervix was very soft and dark coloured. The internal surface of the uterus was softer and darker in colour than usual. The gall bladder large and full; spleen healthy; the left kidney externally natural, its pelvis large, and it contained a creamy coloured fluid; right kidney smaller than usual and contained a similar fluid; the legs very œdematous. Pelvis removed, found an excessive quantity of fat about the pelvis and back.

Pelvis.—Brim tripartite in shape.

From upper edge of the 5th lumbar vertebra to the inner surface of the symphysis pubis 2 6/8 inches.

From side of the said vertebra to the ilium behind the acetabulum on the left side 5/8 of an inch.

From side of the said vertebra to the ilium behind the acetabulum on the right side 1 1/8 inch.

From the inner surface of the pubes anteriorly, to the acetabulum on the right side 3 7/8 inches.

From the inner surface of the pubes anteriorly, to the acetabulum on the left side, 3 1/2 inches.

Cross measure of the widest portion of the anterior slit 5/8 of an inch.

Cross measure at the point of anterior slit 2/8 of an inch.

Outlet.—From the point of the coccyx to the lower edge of the symphysis pubis 2 5/8 inches.

From the widest part of the anterior slit to the coccyx 1 2/8 of an inch.

Depth of the anterior slit 2 inches.

Between the anterior edges of the tubera ischii 1 6/8 of an inch.

Between the posterior edges of the tubera ischii 2 1/2 inches.

From the right spine of ischium to the coccyx 6/8 of an inch.

From the left spine of ischium to the coccyx 5/8 of an inch.

Depth of the fore part of the pelvis 3 5/8 inches.
,, lateral part of the pelvis 3 6/8 ,,
,, posterior part of pelvis 3 ,,

Distance externally between the bottoms of the acetabula 1 7/8 of an inch.

Distance internal measurement 1 3/8 of an inch.

Distance between the superior spinous processes of the ilia 7 1/2 inches.

Distance between the inferior spinous process of the ilia 4 7/8 inches.

Distance between the centre of the crests of the ilia 10 inches.

Distance from the upper edge of the 4th lumbar vertebra to the inferior spinous process of right ilium 1 6/8 inch.

Distance from the upper edge of 4th lumbar vertebra to the inferior spinous process of right ilium, 2 6/8 of an inch.

Remarks.—Mollities ossium, under which this woman suffered, usually commences during pregnancy, but in her case it most likely begun at the time she first complained of pains in the back and hips. The disease most probably made little progress until her second pregnancy, when no doubt it was much aggravated, but its ravages on the pelvic bones were chiefly made during her last gestation. Some of her relations had suffered from rheumatism, and it was said that she had laboured under the same complaint, but for anything I know to the contrary, they (her relations) might have had the disease now under consideration. The predisposition then (most likely hereditary,) remained comparatively undisturbed, until roused into activity by those changes which are produced on the vascular and absorbent system by impregnation. Her occupation as a weaver no doubt greatly contributed to increase the degree of pelvic distortion. The projection of the promontory of the sacrum and lumbar vertebræ mechanically impeded the passage of the fæces into the rectum, which in such cases is always an additional cause of constipation, and which almost invariably occurs, to a greater or less degree, in ordinary pregnancies.

The enema apparatus should have a long flexible tube, (like that which is passed into the stomach to throw fluids into it,) so that its point can be carried beyond the altered pelvic brim. An ordinary female

catheter is too short to answer its purpose in cases of this sort, it should be equal in length to that of the male. By the deflected state of the uterus the bladder is forced forwards and downwards, whereby its cervix is lengthened and compressed upon the pubes. This altered position of the bladder requires a different method to pass the instrument. The point being introduced into the meatus, (which lies in the upper part of the anterior pelvic slit, and a little behind the lower part of the symphysis pubes,) the hand part must then be depressed and carried backwards towards the extremity of the coccyx, and the instrument must afterwards be cautiously moved on into the bladder.

The stethoscope affords us information of two kinds—positive and negative; in its application here we only derived the latter kind. The pulsations of the infant's heart could not be heard, and from the absence of its sound, coupled with the odour of the vaginal discharge, we concluded it was dead. The functions of the placenta had long ceased, and therefore no *soufflet placentaire* was audible, so as to point out to us the location of this organ. If it had been otherwise, I might, and indeed ought, as far as possible, to have made the incision into the uterus, so as to avoid cutting on and into the placenta. The importance of such a procedure I had stated, before the operation, to Mr. Dunn, and requested that he would, as expeditiously as possible, extract the infant, and at the same time pass one hand to guard its neck from spasmodic seizure by the uterus, if perchance I should unfortunately cut upon the placenta. I have elsewhere (*Edin. Med. and Surg. Journ.*, Vol. 60, p. 67,) ventured to state this, (the incision and consequent partial separation of the placenta,) as the cause of this irregular contraction of the uterus. If the child had been alive, most likely such a grasp would have destroyed it before it could have been extricated.

It is to be lamented that the existence of labour had not been earlier known, as perhaps a different termination would have taken place. To wait for the changes which usually occur in the os uteri, during the first stage of normal labour, is a great mistake in those cases in which there exists extreme pelvic distortion. This part of the uterus is not often to be felt, and when it is accessible it is found a little open, its full dilatation having been prevented by the vicious conformation of the brim of the pelvis. The evil arising from this procrastination ought to be a beacon to us in future, and guard us against vainly waiting for such a change. The highly inflamed state of the bowels which existed before the operation, and their pathological condition after death, together with that of the os and cervix uteri, &c., afford indisputable evidence of the mischief which had been inflicted during her protracted labour.

The term protraction should be relatively considered; a woman (as in this case) in a bad state of health cannot safely endure the same degree of pain, or for the same length of time as one who is well; nor will the os and cervix uteri bear pressure very long, without structural injury.

Surely there is here sufficient proof of the necessity of the Cæsarean section, for neither the presentation of the infant nor the os uteri could be touched. Independently of these circumstances I am bold to assert, the delivery could not have been performed by the perforator and crotchet, even if assisted by the marvellous power of the osteotomist, provided the implements were used by the most experienced and celebrated anti-Cæsareanists. No practitioner, then, however warped his opinions are, will presume to attribute the death of this poor creature to the operation; but on the contrary, will place the case in the catalogue (already too great) of those in which death has happened in consequence of having too long deferred its performance.

ON

GOUTY INFLAMMATION ATTACKING THE STRUCTURES OF THE EAR.

By WM. HARVEY, Esq., M.R.C.S.L.,

SURGEON TO THE ROYAL DISPENSARY FOR DISEASES OF THE EAR.

Gouty inflammation of the ear, whether it attacks the external or internal part of the ear, always appertains to the uncertain class of suspicious diseases, for if the patient be really re-established in health, still he is never secure from relapses. The prognosis is most favourable when the inflammation is seated in the external part of the ear, when the individual is young and strong, and is in such a state that everything necessary for his cure can be applied. It is less favourable if the patient is very weak and sensitive, is advanced in years, or of a cachectic habit, and has been frequently exposed to attacks of gout; changes have then taken place in the meatus and membrana tympani, whereby the nutrition of these parts, as well as the function of hearing, becomes injured. The internal gouty inflammation of the ear yields an unfavourable prognosis, for in it such disturbances and total changes of the tissues and structures take place, are followed, if not by complete deafness, at least by an extreme degree of hardness of hearing.

In the treatment of gouty inflammation of the ear, the first care of the surgeon should be to see that the patient is withdrawn from the noxious influences which first occasioned the disease, and that the inflammation is checked. In order to attain this end, every action of cold damp air, and above all, of everything which might promote or add to the congestion of blood in the head and ears, must be avoided; on the contrary, living in a dry, temperate air, spare diet, food easy of digestion, and perfect rest of mind and body, are recommended. It is easy to see that in the commencement the so-called antiarthritics, which in general belong to the class of the exciting medicines, are not applicable, and that only an appropriate antiphlogistic mode of treatment is admissible. In this case one must be directed partly by the age and constitution of the patient, partly by the seat and degree of the inflammation, as well as by the

violence of the accompanying fever. If the inflammation of the meatus be slight, no blood-letting is required, but if it present a violent character in all its phenomena, it should be reduced by local blood-letting,—by means of leeches placed around the ear. But if the inflammation has seized on the internal ear, and has attained considerable intensity, then, in case the patient is strong, plethoric, and not advanced in years, the practitioner may employ a proportionately copious venesection; he should, according to the violence of the local symptoms, place a greater or less number of leeches around the ear, and apply the cupping glasses to the nape of the neck, to the shoulders, and the spine. In weak and elderly individuals, and where the inflammation is not violent, or is chronic, leeches or cupping-glasses suffice. Internally we should prescribe mild antiphlogistic aperients in such cases, so as to produce copious evacuations by stool, and a derivation from the head and ear as quickly as possible. After the inflammation has been moderated, it is very easy to remove it entirely from the ear. Together with careful attention to the bowels, remedies which moderately promote the cutaneous transpiration are subservient to this end, accordingly I have found the continued administration of guaiacum, combined with alkalies and colchicum, or ammonia, the most efficient remedies; at the same time we should not neglect repeatedly to employ cutaneous irritants which derive powerfully, namely, acrid foot-baths, sinapisms, and blistering plasters to the nape of the neck, and to the shoulders. Should the inflammation of the ear be a consequence of a suddenly suppressed action in any joint whatever, we should apply here a cutaneous irritant, which may act rapidly. In less urgent cases we may employ frictions of croton oil, or tartar emetic ointment, over the region of the mastoid process, and on the nape of the neck, blisters to be kept open, issues on the upper part of the arm, and setons in the neck. If by the internal treatment the inflammation is crushed, and one has now to do only with the after-consequences of the same, then we should direct our efforts against the gouty disposition, and seek to ward off relapses; we should, accordingly in the first place, prescribe an appropriate dietetic line of conduct, recommend the use of food simple and easy of digestion, forbid strong bear, acid and heavy wines, liquors and other such drinks, as well as all heating, flatulent, fat, salted, and highly-seasoned food. The patient should take sufficient bodily exercise, not tarry too long in bed, clothe himself sufficiently warm, in order to protect himself from catching cold, cover the head with a warm cap, and use friction carefully over his body.

In order to remove the disturbance in digestion, the acid formation of mucus, obstruction, &c., those resolvent and bitter remedies so frequently celebrated in gout, will be found serviceable, as the infusions, decoctions, and extracts of taraxacum. Several aperient and diuretic mineral waters act very beneficially, more especially in the case of congestions in the head. To act on the lymphatic system and the excretions generally, sulphur will be found useful. With respect to the local treatment of arthritic inflammation of the ear, whether the external or the internal parts of the ear be affected, nothing further is to be done at first except to cover the ear and the entire side of the head affected with warm dry cloths and the like. Every moist application is carefully to be avoided, as neither the lesser nor the greater degree of arthritic inflammation of the ear will admit of any such. In order to remove the morbid sensibility of the nerves of the ear, we may rub into the parts surrounding the ear the fluid ointment mixed with opium or extract of belladonna, or allow a solution of one grain of morphia in half an ounce of olive oil to be dropped in. In case of abscess forming in the meatus, and suppuration in the cavity of the tympanum, much relief will be afforded by a free liberation of the integuments covering the mastoid process, and kept discharging by a sponge tent in the wound for some time after; soothing and anodyne vapour and poultices are to be employed. Should a purulent discharge have established itself, the meatus must be carefully dried and covered with a compress or the like. Obstinate ulcers in the meatus should be treated with the tinctura opii camph., and even with the lapis infernalis. Should any affection of the mucous membrane set in, it is to be treated in the same way as in the case of the common catarrhal otitis. In order once more to awaken the sensibility of the ear, which has been changed by inflammation with respect to impressions coming from without, benefit will be derived from frictions with the volatile liniment, opodeldoc, oleum cajeput, &c.

2, Soho Square.

[To be continued.]

ON THE

TREATMENT OF THE VARIOUS FORMS OF HERNIA

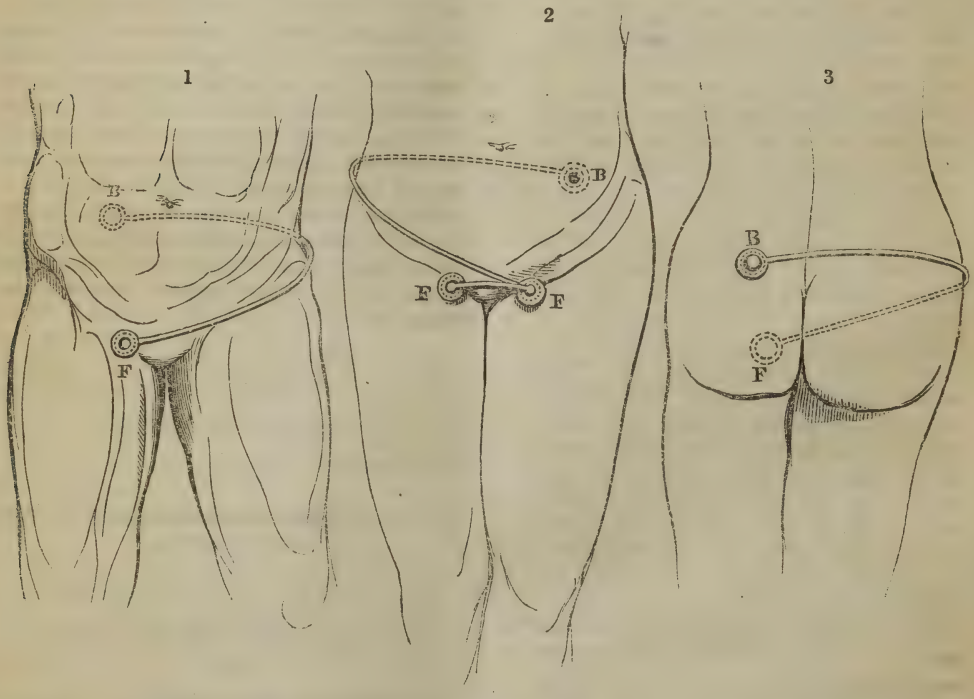
BY NEWSON'S PATENT WIRE TRUSS.

By FREDERICK H. HEWITT, M.R.C.S.

Of all the diseases and infirmities that flesh is heir to, there is probably not one as widely prevalent as hernia. Upon the most moderate calculation there must be at least 100,000 ruptured persons in the metropolis; and in some parts of the country the proportion is said to be much greater. When we reflect that all, or nearly all, such persons come sooner or later under the notice of a surgeon, it does certainly seem strange that there should be so little unanimity among the profession as to the best way of relieving and, when practicable, of curing the complaint by mechanical means. Perhaps the explanation of this apparent anomaly is to be found partly in the great and perplexing variety in trusses, and partly in the limited number of cases which come annually under the observation of most practitioners, who are glad enough to

simplify the matter by recommending one particular kind of truss (as Egg's, Coles', or Salmon's,) in every case; or by leaving it to the truss-maker to construct the truss in any way he may think best. My object in the following remarks is to introduce to the notice of the profession an instrument already very favourably known to several leading physicians and surgeons in London under the name of "Newson's Patent Wire Truss." My own experience of it comprises at least one hundred cases, including every variety of hernia to which a truss is applicable; and without claiming for it anything like infallibility, or even universal applicability, I believe it will be found to combine comfort and efficiency, together with the minor qualities of lightness and simplicity, in a higher degree than any other instrument of the kind, especially in difficult cases.

A glance at the drawings will at once explain its construction. It consists of two pads, one resting upon the hernia, the other upon the opposite point at the back of the pelvis, connected by a round or wire spring, which passes round the hip *opposite* to the hernia. That part of the spring which crosses the spinous processes is always curved just enough to leave an interval of one-eighth to one-fourth of an inch between it and them, and is on a plane higher than than that which crosses the middle line in front. Even the double truss passes round one hip only; in fact, it differs from the single one only in the addition of the little supplemental spring F F, which is generally so adjusted that the pressure upon the pad at its extremity shall be rather less than that exercised by the one at the end of the longer, or mainspring. In *fig.* 2 the left hernia is supposed to require the greater pressure. The pads are made of various shapes—round, oval, pear-shaped, &c.; but for ordinary purposes the round ones are found to answer perfectly well.



The apparent resemblance to Salmon's truss is so obvious, (except as regards the double truss,) that I cannot better describe the principle of its action than by noticing very briefly the particulars in which they differ. They have in reality only one feature in common, viz., the opposite sided mode of application:—

1. The pads are fixed, instead of being connected to the spring by ball and socket joints. It has always appeared to me that the substitution of a moveable for a fixed pad was rather a *disimprovement* than otherwise. It increases the self-adjusting power of the instrument, but it renders the pressure shifting and uncertain, by enabling any part of the circumference of the pad to yield to any sudden impulse from within, instead of resisting it. Hence a much stronger spring is required, especially for a bad hernia, than if the pads were fixed. The most powerful truss I have ever seen was one constructed on Salmon's principle for a large entero-epiplocele. It had caused severe ulceration from the groin to the hip, but had never retained the rupture for many hours together. In the "wire truss" the ends of the spring are left soft enough to admit of their being bent or twisted by a moderate force in any direction. In this way the plane of the pad's surface may be adjusted with the greatest nicety, so that either the pressure may be equally distributed, or, if required, may be concentrated upon any particular point; as over the internal ring if the hernia is recent, over the external ring and inguinal canal if it is direct, whether originally or from neglect or mismanagement.

2. The spring is a round or wire spring instead of a flat one. The advantage of this is, that its diameter being the same in every direction it can be moved with almost equal facility in every direction. Thus the pads can be moved, not only towards or from each other, (like a pair of sugar tongs,) but if one be fixed the other can be moved up or down, or even in a circle. And, accordingly, when the truss is carefully applied, the back pad may be moved up or down to the extent of two inches, or even more, without disturbing at all the front pad in the groin; and it is found that it is always the back pad which is affected by any sudden movement of the body. This substitution, therefore, of a round, for a flat spring, confers an amount of self-adjusting power, sufficient to render any joint between the spring and the pads unnecessary.

3rd. There is no pressure upon or within two inches of the spinous processes. And not only is this avoided by slightly curving the posterior half of the instrument, but by thus crossing the median line both before and behind it, it obtains so firm a hold upon the pelvis as to render any strap or fastening between the two ends of the spring unnecessary, except in cases of extreme emaciation.

4. Even the double truss, as already stated, leaves one hip free.

It should have been stated that pressure upon the abdomen is as scrupulously avoided as upon the spine, the curve of the anterior half of the instrument being carefully adapted to the shape of the wearer, and the more powerful the pressure required, the more loosely is the truss made to fit round the pelvis; in this respect it is just the reverse of the majority of trusses, in which the pressure is increased by tightenimg the straps and compressing all the parts surrounded by the instrument.

The following cases will I think suffice in the way of illustration:—

Case 1.—H. Langford, aged 73, became the subject of a left inguinal hernia, thirty-five years ago, neglected it, and it soon descended into the scrotum. Has had trusses from every society in London, some of them very powerful, and with every variety of straps and fastenings, but for the last thirty years it has been constantly in the scrotum, except at night. When he first applied to me, it was of great size, completely filling half the scrotum, and had become to all intents and purposes direct; the points of two fingers could be passed through the ring apparently straight into the abdomen. There was also a small right inguinal hernia. He has now worn one of Newson's double trusses for nearly two years, and it has been only upon some very unusual exertion, in unloading vans, &c., that his hernia has escaped. The most violent coughing seldom or never produces any effect. The parts, too, have so contracted, that the hernia cannot now be made to descend to anything like the same extent as at first, even when the truss is removed.

Case 2.—Anne Sallaway, aged 45, has had a femoral hernia for the last eight years; it was small at first, but soon increased in size. She had two trusses from the society in Hatton Garden; neither, however, were of the slightest use. Four years ago it became strangulated, and she was operated upon in Guy's Hospital by Mr. Bransby Cooper. After the operation it became larger than ever, and after repeated attempts to obtain an efficient truss from the two well-known instrument makers at the west end, she gave it up in despair. When I first saw her the hernia was of the size of a small apple, and the crural aperture admitted the point of my thumb for nearly an inch. The only difficulty met with was in avoiding pressure upon the hip, owing to a peculiarity in the shape of her pelvis. The hernia was completely retained from the first, and is now so much reduced in size as to require but very slight pressure.

Case 3.—J. G., aged 46, admitted into University College Hospital under Mr. Quain for hydrocele. The following was the report on his admission:—"Scrotum as large as a full-sized hat, twenty-one inches in circumference, and at its upper part the hydrocele is covered largely with bowel in a hernial sac." He was tapped three times. At the first operation seven, at the second four pints, and at the third one pint, were drawn off. The following was the report when he was discharged:—"There is no deformity; the scrotum on the whole is larger than natural," &c., &c.; "the bowel, which had been almost constantly during several years in the scrotum, is now retained in the abdomen with one of Newson's wire spring-trusses." When this man was first sent to Mr. Newson by Mr. Quain, his case was unusually embarrassing, owing, not only to the great size of the ring, but the distortion of the parts, which had not yet subsided.

Clapham, Surrey, May 3, 1851.

ON THE AFRICAN FEVER.

By HENRY LANDOR, Esq.,

LATE COLONIAL SURGEON TO THE GOLD COAST.

The opinions of nearly all medical men who have practised in hot countries seem to be against the contagion of fever, whether it be called plague, or cholera, or yellow fever, or the African variety of the disease. These opinions, and the practical results to which they lead, are admirably condensed in the "Report on Quarantine," issued by the Board of Health, and printed by the authority of Parliament.

It seems, also, to be the general opinion that there is only one fever poison, and that local or atmospherical circumstances determine the type the disease will assume in each epidemic. In the present state of our knowledge it is impossible to determine what these local circumstances are with sufficient exactitude to guide the sanitary practitioner; but it is somewhat easier to find out what they are not; and the considera-

tion of the negative may eventually lead us to the knowledge of the positive. We all admit the influence of dirt, famine, and want of ventilation in increasing the virulence of every epidemic. We likewise have an impression that fevers of the intermittent variety, in particular, owe their severity, if not their origin, to decaying vegetation. It is my object to bring forward some facts to show that this is by no means the case, and that if decaying vegetation encourages the ravages of the epidemic, it is exactly in the same manner that filth, famine, and want of ventilation do the same, and not as the cause of its origin. The poison of fever arises from some general cause not yet known. The circumstances that favour its distribution are more within our present means of observation, and when these are accurately determined, the true origin of the disease will be more easily discovered.

I purpose in this paper to give some account of the African fever as it is known on the west coast. It prevails within the warmer latitudes from the desert on the north to the borders of the Cape Colony. It is as fatal in the Gambia, at Sierra Leone, as at Cape Coast Castle, or at Bagagry; yet the physical circumstances of the country widely differ at all these points. From Cape Palmas to Cape St. Paul, which includes the Gold Coast, the geological formation is the primitive, stratified, the usual formation of gold deposits. This formation is necessarily the driest of all the geological series, for it is exceedingly porous, and hardly capable of retaining water on its surface. In countries of this formation, if situated in warm latitudes, the rivers rarely, if ever, run all the year. The rivers are mere surface drains, and carry off only the surplus of excessive rains; consequently, when the wet season departs, general dryness prevails. Now this is the state of things from Cape Palmas to Cape St. Paul. There are no rivers broader than the Thames at Windsor, no extensive marshes, no mangrove swamps, and yet the African fever prevails as extensively and is quite as fatal as it is in the wettest part of the coast. No decomposing vegetation exceeding that of the average of DRY tropical countries prevails to countenance the opinion that such is the origin of the disease. On the contrary, the surface of the country is not covered with thick herbage or decaying leaves, nor is the soil of that deep loamy character, resulting from vegetation, which characterizes the interior of the Brazils; yet the latter is free from fever, while the former is infected with it. On the Gold Coast the disease generally puts on the intermittent character markedly, yet in what are called bad seasons it becomes remittent, and in most of the rapidly fatal cases is continued; and occasionally even it assumes the appearance of yellow fever, with the coffee-coloured vomit and a yellow skin, and a fatal termination in three or five days. It is supposed to be extremely fatal once in seven years, when the mortality is generally 50 per cent., often more, while in ordinary years it seldom exceeds 25 per cent. However, it is not my object to describe the fever, but to show that it is not dependent on vegetation. The mortality on the Gold Coast is not exceeded on any part of the coast; it is not greater at the Gambia, where vegetation is denser, nor at Sierra Leone, where the Bulam shore, a region of swamps, is supposed to cause it, nor at that part of the coast from Cape St. Paul to the Calabar, which includes the whole delta of the Niger. Now surely this ought not to be if the general opinion were the correct one.

Moreover, when I was at the Cape de Verdes in 1841, the islands were suffering severely from fever of this very African type, consequent on a famine of great severity, such as, but more than that, which now prevails in the island of San Nicolas amongst the same group. But mark! the famine was caused by a drought of many months' duration, and the fever accompanied this state of things; but if decaying vegetation were the cause, it should have arisen after an extremely wet season, not a dry one. In the whole island of St. Jago there was not herbage enough to feed the miserable lot of cattle and goats that had survived the drought, and the inhabitants were keeping them alive on the succulent stems of the plantain. The island is a mass of volcanic scoria, with a few cocoa-nut and tamarind trees, and bananas in the valleys; and I was taken to a valley to see one poor wretched stream of water, about a yard across, which was exhibited as a curiosity, and which, after running a mile or two, lost itself in the scoria. Surely this is not the state of country generally supposed to cause fever, but the reverse. The acting Consul, (the Consul himself having the fever, and having gone to a more westerly island for improvement,) told me that his father had removed to be farther from the African coast, the proximity of which he supposed had caused the fever in St. Jago; but this is obviously a mistake, as the opinion of every medical man employed in the squadron is, that forty miles from the coast of Africa the crews do not become infected with fever, and this opinion caused Sir Charles Hotham to order his vessels to keep about that distance at sea. (*See his evidence.*) The most easterly of the Cape de Verdes is many hundreds of miles from Africa, and I am convinced that Africa had no more to do with the origin of fever in those islands than England had; in fact the fever-poison, however, that may arise, found in the islands themselves favourable circumstances for its development, and fever succeeded, as it always does succeed, famine and privation, whether in the Cape de Verdes or in Ireland. The local circumstances of the islands favoured it, as no place exceeds Porto Peaga in filth; indeed, bad houses, dirt, and bad feeding, were common to the whole island, and are the characteristics of Portuguese habitations in Africa and in the Brazils. The wonder is, not that fever prevails, but that it is ever absent. No one acquainted with African towns can fail to perceive the abundance of dirt within them; no drains, abundance of cess-pools, no privies, and crowded habitations, and probably, more than all, the pernicious custom of burying the dead under their houses, are all most suitable provocations of pestilence. Every African family bury their dead beneath the lower floor of the family house. If church yards are evils in a city, what would be the condition if the dead of each

house were superficially buried beneath the kitchen floor?

The circumstances here detailed—the prevalence of fever in dry countries equally as in wet—prove, I think, that whatever may be its source, decomposing vegetation is not that source, and show that, although decomposition may be favourable to its development, it is so in just the same manner as dirt, famine, or want of ventilation.

Time may make us acquainted with the changes in the atmosphere produced by electricity and other subtle agents, and explain to us the laws of such changes, then we may see the reason of the periodicity of fatal seasons at present concealed from us. Our knowledge is not sufficiently advanced to enable us to discern these things now; but it is much and useful, as I said at the commencement, to find out what is not correct, for displacing an erroneous opinion is a great step towards attaining a true one.

I may add as a corroboration, that in Western Australia large and extensive swamps abound, and much mangrove muddy country, yet no one ever heard of a virulent fever; and Europeans are constantly in the habit of sleeping near such swamps, but they never have fever.

Heigham Retreat, Norwich,
May 10, 1851.

CURIOUS TRAIN OF SYMPTOMS CONNECTED WITH A CLOT IN THE MIDDLE LOBE OF THE CEREBRUM.

By HENRY COOPER, Esq., Lond.,
PHYSICIAN TO THE GENERAL INFIRMARY, HULL.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—The following case has been one of great interest to the medical men in charge of it during its long and painful progress; if you think it will be so considered by your readers, it is very much at your service. The case is remarkable as shewing the variety and importance of diseased actions which may result apparently from the same cause, such diseases, though varying in seat and intensity, still maintaining the same general congestive character.

The subject was a lady, 35 years of age, of spare habit, active, intelligent, and of exciteable temperament. She had borne several children, and enjoyed good health, but for the last few years had undergone much anxiety and fatigue in nursing. In the winter of 1848-9 she was knocked down by a carriage and sustained some injury of the head. In the autumn of 1848, she had a severe attack of the malignant cholera then fatally prevalent. She rallied from the congestive stage of this disease and made a satisfactory convalescence. An attack of epistaxis occurred in Jauuary, 1850. In the spring of 1850 she was suddenly attacked with epileptic coma, while still subject to much harass of mind and body. The seizures which I witnessed at a later period of the illness, commenced with convulsion, coming on much as in ordinary epilepsy, generally with little or no warning; they continued three to five hours, and were so violent and long continued as to threaten to destroy life either by asphyxia or exhaustion of vital power. The means used exercised little control over the paroxysm till its usual term of five hours had expired, when the patient sunk into a deep and unrousable torper. In twelve to twenty-four hours this state was succeeded by delirium of a wild character, not unlike delirium tremens, accompanied with wakeful nights; after which a long deep sleep put an end to the attack, and extreme prostration and partial amaurosis of the right eye alone remained. The whole attack would last four or five days. The paroxysms occurred at variable periods of three or four weeks.

In November, 1850, this lady's life was further placed in jeopardy by epistaxis, which had gone on to a frightful extent before assistance arrived. Plugging of the posterior nares and the most careful restorative measures brought her through this danger, and it was hoped that an immunity had thus been ensured against the cerebral attacks.

In the early part of December we were surprised by another seizure equally violent and sudden with those which had preceded, but in a totally different seat. This was spasmodic asthma with intense dyspnœa, deep congestion, and sudden œdema of the superior extremities. From this desperate condition she again rallied, but there remained some dyspnœa, copious expectoration which became rusty, frequent spasmodic gasps in the breathing, and a dull impermeable patch in the back of left lung. During the whole of this time her intellect remained clear, though she manifested irritability and peculiarities of temper not natural to her.

We now come to the last phase of this long course of suffering. While slowly recruiting from the congestive attack on the lungs, she had one evening a convulsive paroxysm, of much less than usual severity, and in the morning was found paralytic of the right side. From this state she also slowly recovered, but the powers of life were now worn out with the long struggle; her mind became fatuous, with occasional maniacal delirium, and she died seven days after the last attack, and eleven months after the first epileptic seizure.

The *post-mortem* examination showed very great congestion of the external vessels, of the scalp, and of the scull and its membranes. The blood was fluid, and ran from the incisions in a stream. The brain was firm and healthy, and not unnaturally vascular; nor did it present any unusual appearance till the middle lobe was sliced, when a solid, firm, palish, fibrinous clot, surrounded with a discoloured margin, was found imbedded in the white matter under the thalamus of the left side; it was of an irregular oval shape, one inch long, by somewhat less than half an inch broad, its long axis looking upwards and forwards. There was little fluid in the ventricles. The plexus was pale, but the arteries at the base of the brain was somewhat thickened. The lungs were somewhat œdematous. The heart was

large, and the left ventricle was thickened distinctly, but not excessively.

In reviewing the incidents of this case, the question naturally suggests itself, in what manner are the *post-mortem* appearances connected with the singular series of changes exhibited in the history of the disease. The first epileptic seizure was probably directly consequent on the effusion of the clot, and this again may be fairly attributed to the impetus of the hypertrophied heart, and the changed mechanical properties of the vessels of the brain, which so commonly accompany that disease. The appearance of the clot favoured this view of its date and history. In this case it is obvious that the clot acted as a predisposing cause only in the subsequent abnormal movements of the nervous system, the proximate cause being temporary congestion, either produced by the overactive heart, or by sympathy with other organs in a disordered state.* The diseases throughout assumed a *marked congestive* character. The abdominal viscera, the brain, the lungs, and the heart, becoming each in its turn the seat of this congestion.

I may add, that depleting measures were principally resorted to, the violence of the attacks prohibiting temporizing measures. Opium produced no effect. Cupping, with or without the scarificator and purgatives, were found the most effectual means.

I remain, Sir,

Your obedient servant,

HENRY COOPER, M.D., Lond.

Hull, March 1, 1851.

* Dr. Bright, in his "Reports of Medical Cases," gives a case of convulsions with apoplexy in which the clot was in the cineritious substance, (p. 280, Vol. i.,) and several cases of epilepsy with coma, (p. 198,) which he attributes to congestion in the cineritious matter; probably the latter condition may in this case have supervened at the time of the epileptic seizures.

Provincial Medical & Surgical Journal.

WEDNESDAY, MAY 28, 1851.

In our advertising columns will be found a prospectus of a "Provincial Medical Collegiate Institution," which is intended to be established by Dr. Brindley, of Tarvin Hall School, near Chester, as soon as he can make the necessary arrangements, and, if thought desirable, under the sanction of this Association. The object of this proposed establishment is to afford that preparatory education for boys who are about to enter the medical profession, which is now rendered imperatively necessary by the requirements of the University of London, of the College of Surgeons, and of the Apothecaries' Company, and still more by the increasing competition in the ranks of the profession itself.

Our readers are aware, that at the Northampton meeting in 1844, it was proposed by Mr. Martin to establish a school for the sons of medical men, and a Committee was appointed for the furtherance of the object, which was unanimously considered by the meeting a highly desirable one. The Committee presented the following report in the year 1845:—

"That, so far as the attention of the medical public has been directed to the subject, and opinions expressed on the plan proposed, the latter have for the most part been decidedly favourable.

"On one point only has any objection of importance been offered, and that is, as to the required uniformity of religious instruction in the first proposed school: but the Committee are of opinion that a diversity on this most important subject would be quite incompatible with the harmonious operation of any schlolastic establishment of the kind contemplated.

"They feel assured also, and have no doubt of the concurrence of this meeting, that whatever legislative measures may be adopted with respect to the medical profession, an improved classical and general education will be absolutely required of those youths who are desirous of entering the profession.

"The Committee are further of opinion, that the plan, of which a mere outline only has been offered, is perfectly practicable—is worthy of the support of the profession; and having that support, with united action only, might assuredly be fully realized.

"But, notwithstanding its apparent desirableness, and the favour with which the suggestion was first received, subscriptions to the amoant of £1610 only have been promised.

"They therefore request a more efficient patronage of the plan, now that, for a time at least, there will be less occasion for discussion on the public affairs of the profession. Time will thus be afforded for cool and deliberate thought, on the subject of the preliminary education of the sons of medical men, whether they are destined for the profession of their fathers, or for any other profession.

"The Committee, for the present, rest in the confident hope for a more efficient support of their plan, that they may be enabled, by a proper amount of subscriptions, to invite a meeting of the subscribers, for the purpose of further proceedings.

"Joseph Hodgson, Chairman.
"Thomas Martin, Secretary."

The proposal was, indeed, taken up most warmly by every one who was interested in the education of the rising generation, and only failed for want of funds, the subscriptions which were promised never amounting to more than £1625, whilst £10,000 were considered necessary to start a single school for 200 boys; and at the meeting held at Norwich in 1846, the Committee sent in a report to the effect that the object was unattainable, concluding in the following words:—

"For many months past not a single application for shares has been made, and no new donations have been offered, so that the Committee have at last been compelled most reluctantly to come to the conclusion that the scheme has failed, and must be abandoned. So soon as they have returned the few pounds which have been paid into their hands, which they propose to do forthwith, they will consider their labours completed, and their functions as a Committee at an end. While reporting this result, however, the Committee are still deeply impressed with the great value and importance of the object they sought to attain. They think the project worthy of a better fate than it has met with at the hands of the medical profession, and they still hope that it may at some future day be revived under happier auspices and with a better result.

"JOHN FORBES, Chairman.
"THOMAS MARTIN, Secretary."

It will thus be evident that Dr. BRINDLEY offers to supply a pressing want, which has long been felt, and which has only been unrelieved from the deficiency of support in the shape of pecuniary responsibility. It is of vast importance that something should be speedily done; the stringent nature of the present examinations will prevent all but well-educated young men from passing, unless they devote the time which should be spent in the dissecting room or hospital to the acquisition of that elementary knowledge which a properly organized school can well afford. It is a question whether such a school should be made to supersede the apprenticeship system, or whether it should be only preparatory to that ordeal, and we shall be happy to receive the opinions of our readers on this subject. But whether it displaces the apprenticeship, or is made subsidiary to it, there can be no doubt that there are many subjects, such as the French and German languages, chemistry, botany, elementary mathematics, comparative anatomy, &c., which may be taught most efficiently at such a school, especially if the pupils are left to the age of 18, as is proposed by Dr. BRINDLEY.

It is, however, quite unnecessary to dilate upon the advantages of such a course—they have been long acknowledged; and it will only be for the Association, assembled at Brighton, to consider the propriety of affording their superintending control and support to Dr. BRINDLEY in his new undertaking. There are many advantages in his proposal, some of which are the following:—

1st. An immediate supply of an acknowledged want, without risk or responsibility.

2nd. The guarantee (of previous success in a similar undertaking) that the contemplated plan will be efficiently carried out.

3rd. The offer by Dr. BRINDLEY to engage himself to hand over the school, when fully established, to the Provincial Association, if they desire it.

4th. The proposal to submit all his arrangements to the superintendence of the Council of the Association, or a Committee appointed by them.

It appears to us that the contemplated arrangement would be highly advantageous to the Association; but as it is so completely in its infancy, it is impossible to form more than a general opinion of the probability of its success. Much certainly depends on the energy, ability, and principles of its projector; and here, although we have had no experience of Dr. BRINDLEY as a teacher, we can speak most highly, from long personal knowledge, of his character as a man of indomitable perseverance, great ability, and extensive information on general subjects.

THE attraction of the Crystal Palace is so universally felt, that it is necessary to remind our readers that in making their engagements to see its contents, they should not forget the ANNIVERSARY MEETING OF THE ASSOCIATION, to be held at Brighton, on the 13th and 14th of August next. To those who can only leave home for a limited period, we would observe that the two objects may easily be combined, as Brighton is now reached from London in a couple of hours.

Reviews.

Observations on the Art and Science of Medicine. By WILLIAM WEGG, M.D., Cantab. London: Churchill, 1851.

THE present time is full of startling paradoxes no less in medicine than in politics. Once emerged from the mistaken notions of therapeutical activity, under the dominion of which, sound pathology was compelled to succumb to a pharmakolatry almost amounting to blind superstition, it is now to be feared lest we rush into the opposite and equally mischievous extreme; and led away by the "Will o' the wisp" doctrines of *Young Physic*, trust all to the "natural tendency to recovery," of which it prates,

and so be induced to sacrifice to a phantasm, a wholesome reliance on the medicinal agents, which an all-wise Providence, we may be assured, did not call into being without a definite and a benificent object. Legitimate medicine has of late received great discouragement, not only by the countenance afforded to the fashionable quackeries of the day, but what is worse still, by the sceptical writings of those who should have been her defenders, and who, before they condemned the use of drugs, might well have inquired whether their failure did not arise from inability on their part to wield them effectually, rather than from the intrinsic worthlessness of the agents themselves.

Books like the present are for this reason much wanted at this juncture, as antidotes to the poison of medical infidelity now so widely disseminated, and Dr. Wegg has our thanks for his praiseworthy exertions as a pioneer in the good work. The chief barrier to the onward march of medical science is the want of careful and philosophical inquiries into the action of medicines. In this point we are far in the rear of the other departments of professional study. We can lay our finger with certainty upon a diseased portion of lung no larger than it will cover; we can follow after death the mysterious causes of dissolution beyond the ken of natural vision; but we are bound to confess that a logical intepretation of the action of medicines is yet a desideratum. We will not say that Dr. Wegg's volume altogether supplies this want; to confer so great a benefit on our science, requires many years and many labourers; but he has taken a step in the right direction, and a step which, if actively followed up by himself and others, cannot fail to be productive of the most valuable results.

Saying thus much we shall take leave of Dr. Wegg's volume. We might quote largely and advantageously from his observations, but we prefer recommending them to deliberate perusal. They are written in a thoughtful spirit, and deserve better attention than would be given to a few extracts however judiciously selected.

A Child's First Hour, with suggestions for some alterations in the Management of New Born Infants. Addressed to Young Mothers. By a PHYSICIAN. London. 12mo. 1851.

A MOST useful little book, which should be in the hands of every mother whether actual or in prospect. It is admirably calculated to banish for ever the mischievous practices of the self-opiniated tribe, of which Dickens's Mrs. Gamp is no overdrawn portrait, and may perhaps suggest even to the accoucheur a thing or two which have not before occurred to his mind.

Urinary Deposits; their Diagnosis, Pathology, and Therapeutical Indications. By GOLDING BIRD, M.A., M.D., Assistant Physician to Guy's Hospital. London: Churchill. Third Edition. 8vo.

WHEN a medical work reaches a third edition, it may safely be concluded that it has merited as well as obtained the favourable opinions of the profession. Praise is as uncalled for as unfavourable criticism would be absurd. We shall only therefore state that the present edition bears the marks of having been carefully rewritten, and shews that the author has not allowed the most recent information on the subject to escape his notice.

Proceedings of Societies.

EPIDEMIOLOGICAL SOCIETY.

SMALL POX AND VACCINATION.

THE following questions have been put into circulation by the Epidemiological Society, and we insert them at the request of Sir Charles Hastings, who hopes that the members of the Provincial Medical and Surgical Association will forward their replies before the 1st of July, to the Honorary Secretaries, 38, Berners Street, London.

EPIDEMIOLOGICAL SOCIETY, OR SOCIETY FOR THE INVESTIGATION OF EPIDEMIC DISEASES.

President.—Benjamin Guy Babington, M.D., F.R.S,

Vice-Presidents.—Thos. Addison, M.D. (Treasurer); Richard Bright, M.D., F.R.S.; Sir B. C. Brodie, Bart., F.R.S.; Sir W. Burnett, Knt. K.C.B., K.C.H., F.R.S.; Sir C. M. Clarke, Bart., M.D., F.R.S.; Rev. Thomas Dale, M.A., Canon Res. of St. Paul's; R. D. Grainger, Esq., F.R.S.; Sir Charles Hastings, M.D., Worcester; Sir James McGrigor, Bart., K.C.B., K.C.T.S.; John Nussey, Esq.; Professor Owen, V.P.R.S.; John Propert, Esq.; G. L. Roupell, M.D., F.R.S.; Thomas Southwood Smith, M.D.; Colonel Sykes, V.P.R.S.; Thomas Watson, M.D.

Members of Council.—G. H. Barlow, M.D.; Jacob Bell, Esq,, M.P.; James Bird, M.D.; A. Bryson, M.D., *R.N.*; W. B. Carpenter, M.D., F.R.S.; R. Greenhalgh, Esq.; W. W. Gull, M.D.; A. H. Hassall, Esq., M.B.; E. Headland, Esq.; A. Helsham,

M.D,; T. Hunt, Esq.; J. O. McWilliam, M.D., *R.N.*, F.R.S.; J. F. Marson, Esq.: Henry Oldham, M.D.; W. Percivall, Esq.; G. Pilcher, Esq.; E. C. Seaton, M.D.; F. Sibson, M.D., F.R.S.; E. Sieveking, M.D; J. Simon, Esq., F.R.S.; J. Snow, M.D.; G. J. Squibb, Esq.: William Edward Swaine, M.D.; C. R. Walsh, Esq.

Honorary Secretaries.—J. O. McWilliam, M.D., *R.N.*, F.R.S., and J. H. Tucker, Esq.

(Circular.)

Dear Sir,—A Committee of this Society is now engaged in investigating the important facts connected with Small Pox and vaccination, and they are desirous of obtaining information from every authentic source. It will be in your power to render them most valuable assistance if you will kindly furnish them with answers to any or all of the following questions; and I beg to assure you that the information you thus afford will not only be most thankfully received, but will be carefully acknowledged in the Report which it is the intention of the Society to publish. I hope that it will be convenient to you to return this paper before the first of July next.

I am, dear, Sir,
Your obedient Servant,
B. G. Babington, President.

1.—Have you any record of the cases of Small Pox, which have fallen under your observation whether,
a, Natural;
b, After a previous attack of Small Pox, or
c, After Vaccination,
and if so would you state the number of each kind and any particulars you may be acquainted with, especially with regard to the ages of the patients and the character of the attack in each class of cases.

2.—What has been the mortality in each class that you have specified, and in how many cases, *especially in those after Vaccination*, could the death be fairly ascribed to Small Pox, or to previous, coincident, or superadded disease?

3.—In each case of Small Pox after Vaccination, how long a period had elapsed since the peformance of the Vaccination?

4.—In cases of Small Pox, presumed to be after Vaccination, what was the evidence of the Vaccination having been effective?

5.—Have you any facts to show that the protective or modifying power of Vaccination bears any relation to the *number* of genuine cicatrices left by the operation?

6.—Have you *seen* the Vaccine Disease, and subsequently Small Pox, occur in the same individual, and if so, in how many cases?

7.—Have you ever had an opportunity of watching an Epidemic of Small Pox from its outbreak to its termination, and would you favour the Society with the result of your observations? The Committee are desirous of being informed whether the disease first appeared among the resident inhabitants of the district, or whether it was imported, or produced *by Inoculation?*

8.—Have you any evidence of the spread of Small Pox from the improper exposure of persons labouring under the disease?

9.—In what manner are you in the habit of performing the operation of vaccination? How many punctures or incisions do you make? In a person whom you have vaccinated, what are the tests which satisfy you that the vaccination has been effective?

10.—Are you in the habit of omitting to vaccinate in the winter, and, if so, for what reasons?

CONVENTION OF POOR-LAW MEDICAL OFFICERS.

A third audit of the treasurer's account necessarily leads to a review of the past exertions of the committee, and calls for a notice of the position and prospects of the Convention.

The energy and co-operation which characterized the early efforts of the Association have in a measure flagged under discouragement and hope deferred.

The committee for some time past have felt that the period was approaching for them for awhile to suspend their meetings, if not to resign their trust to the great body of the union surgeons, by whom, in 1847, they were authorized to act. Though the labours of the committee have been nobly seconded by a few of the union surgeons in the provinces, they have not been able to realize anything tangible, chiefly because they have been only partially supported from without, and have wanted the steady perseverance and united personal exertion of the many, which alone can conquer such diffused and deep-rooted evils as the Convention was formed to overcome. The contributions to the funds have been few, if we except the sums subscribed in 1849, when an impulse was given at the meeting over which Lord Ashley presided.

On the 21st April, the treasurer wrote,—"We have over-expended to the amount of £7. 11s. 1d.," and added, with his habitual consideration and liberality,—"This sum I shall be happy, if I may be allowed, to present to the committee." The committee gratefully record this generous offer, but they feel that it cannot be the will of their constituents that it be accepted.

In looking over the list of the names of those who have contributed to the funds of the association, it is matter for surprise and humiliation to see that not more than about 400 out of a profession of 15,000, and only 404 out of the 3,000 union surgeons have come forward in aid of a cause in which the profession generally, and the union medical staff more especially, are concerned.

Whatever feeling of timidity, apathy, or hopelessness may have existed amongst the majority of the profession, the committee, on recurring to the small list of free-hearted contributors to their finances, and of manly coadjutors in their operations, cannot but congratulate those gentlemen on the efforts which they have made to overcome a system so oppressive and unjust as that through which medical relief is administered under the domination of the guardians of the Poor-Law Board. They entertain unshaken confidence in the goodness of their cause, and a full conviction that judicious and well-supported efforts will yet obtain for the union

surgeons the redress to which they are so eminently entitled. At the same time they feel it their duty to urge the Poor-Law Medical Officers, and the profession in general, to consider how much the redress which is sought, and for which so large a sacrifice of money, exertion, and time, has been made by some of their brethren, is within their voluntary grasp, but that it can never be hoped for, so long as the degrading and ill-paid appointments are not merely accepted, but made the objects of eager competition.

During the past three years frequent attempts have been made to call the attention of the Government, and also of the public, to the subject. Earnest applications have been addressed, in writing and by deputation, to parties of influence in the Colleges and the Hall—to the Poor-law Board, to the Home Secretary, and to the First Lord of the Treasury. Petitions have been again and again addressed to the House of Commons; the public has been appealed to by advertisements, by addresses, and by reports, which have been seconded by leading articles in many of the most influential journals. These varied efforts cannot have failed to prepare the country for amended legislation; and the speeches of Lord Ashley (in Feb. 1849), and of General Sir De Lacy Evans and Dr. J. Arthur Wilson, at the recent interview with Lord John Russell, are proofs of the cordial and stirring sympathy already awakened.

Under the present political aspect, the Committee have thought right to suspend their meetings until some special circumstance may determine the time for resuming their exertions. They have consequently discontinued the expenses which secured the services of their assistant-secretary. Through the liberal consideration of the Council of the National Institute of Medicine, who all along have placed at the disposal of the Committee their eligible rooms in Hanover Square, they have been saved a considerable outlay for offices. This courteous assistance has been specially noticed by a vote of thanks from the Committee, which they have pleasure in thus publicly recording. The cordial thanks of the Committee have likewise been voted to their excellent treasurer, Thomas Martin, Esq., whose numerous engagements have obliged him to resign the office.

Contributions in aid of past and future expenses, for printing, advertisements, &c., (charges inseparable from the operations of the committee,) are solicited, and may be sent by post-office order to Mr. Lord, who, on the resignation of Mr. Martin, obligingly consented to unite the treasurer's duties with those of the honorary secretary.

The Treasurer's Report of Receipts and Disbursements from the 19th February, 1849, to the 17th April, 1851.

Receipts.	£.	s.	d.
Amount of subscriptions received from 404 contributors	247	14	1
Balance due to the Treasurer	7	11	1
	£255	5	4

Disbursements.	£.	s.	d.
Balance due to the Treasurer, as per last account	22	17	9
Printing	63	0	11
Stationary	7	15	11
Postages	28	18	0
Advertisements	47	17	6
Room and incidental expenses for deputations	3	11	0
Messrs. Fuller & Saltwell's fee	1	1	0
Salary of the Assistant-Secretary	65	0	0
Miscellaneous expenses	15	3	3
	£255	5	4

We, the undersigned, having examined the foregoing accounts with the vouchers, do find the same correct, and that the balance due to the treasurer is seven pounds eleven shillings and one penny.

John Propert,
George James Squibb, } Auditors.

By order of the committe,
Thos. Hodgkin, Chairman.
Chas. F. James Lord, Hon. Sec.

Note.—It is requested that all communications be addressed to the honorary secretary, Charles. F. James Lord, Hampstead, and that post-office orders may be made payable to that gentleman, at the post-office, Hampstead.

FRANCE.

On the Urine in Delirium Tremens.

M. Michea has remarked, that in delirium tremens the reaction of the urine differs widely from that of health. In the healthy state, on the admixture of caustic ammonia, the urine becomes milky and opaque, and deposits the phosphate of ammonia. With oxalic acid an abundant precipitate of the oxalate of lime is formed. In cases of delirium tremens no such phenomena occur. So long as the cerebral disturbance continues, neither of the above reagents cause any opacity in the urine, but as soon as convalescence commences, precipitates appear. From these data he establishes the two following propositions.—1. The phosphates are diminished in delirium tremens. 2. The return to the normal condition of the urine as regards the phosphates, is one of the critical signs of the disease.

M. Michea asks whether these facts throw any light on the etiology of delirium tremens, but at present does not reply to the question. He thinks, however, that the facts may offer some indication for treatment, in the suggestion of allowing animal food as the chief source of the phosphates. The absence of these principles from the brain, he explains by the fact that drunkards have habitually bad appetites, and that when delirium ensues they frequently abstain from food, and especially animal food, for days. They thus deprive themselves of the source whence the phosphatic elements of the urine are derived.—*Revue Med. Chirurg.*

[It is but justice to Dr. Bence Jones to state, that he has long anticipated the observations of M. Michea as regards delirium tremens; but he has shown as far as our memory serves us that a deficiency of phosphates in the urine, is also observed in other diseases of the nervous system, which, if correct, would militate against M. Michea's theory of the cause of their deficiency.—Ed. P. J.]

The Syphon Douche.

This instrument, which has lately been brought forward by Mr. Jones, as an original invention, but which was, in reality, devised by Leroy d'Etiolles as

long ago as 1825, has been much improved upon by M. Blatin, by the addition of an ovoid expansion of the larger tube, by pressure of which the contained air is expelled, and the water from the receptacle introduced. In Mr. Jones's instrument the exhaustion is effected by suction, and unless adroitly done, the patient stands a good chance of having a general, instead of a local, shower-bath. By M. Blatin's modification all difficulty is abolished. In the engraving which accompanies the notice of this instrument (*Gazette Médicale,*) the similarity of the original to that which Mr. Jones has appropriated, is at once evident.

A new plan of Reducing Paraphymosis.

In spite of the many proceedings occasionally adopted for the reduction of paraphymosis, the operation is at all times painful to the patient, and disagreeable to the surgeon; M. Mercier, therefore, thinks he is doing the profession a service in promulgating the following plan:—In all operations for paraphymosis, the great obstacle to reduction arises from the fact, that the manipulations, while they compress the glans in one direction, expand it laterally, so that there is equally an obstacle for the contracted and infiltrated prepuce to overcome. Although the infiltration is greater on the inferior aspect of the penis than elsewhere, it is not there that the difficulty lies, but above, on the upper aspect, where the corona glandis rises perpendicularly. M. Mercier's idea is to render the reduction of the prepuce more easy by converting this perpendicular elevation into an inclined plane, in the following manner:—He stands on the right of the patient, placing the index and middle finger lengthwise under the penis and the thumb above, thus making pressure, and at the same time forcing his thumb-nail beneath the constriction. With the left hand he then makes circular pressure over the tumefied prepuce and the fingers below it, at the same time drawing the constricting band further on to the thumb-nail, and causing the glans to glide backwards over the pulp of the thumb. The reduction is thus effected.

On Uterine Engorgements.

In a paper published in the *Presse Médicale,* M. Thiry admits three varieties of uterine engorgement—the congestive, the inflammatory, and the hypertrophied. In the first variety the congestion may precede or follow an inflammatory condition. It consists in more or less afflux of blood to the vessels of the organ, and may be divided into three sub-varieties. It is *active* when it arises from direct stimulation, as from violence, excessive intercourse, or the use of pessaries. It may also be induced by the menstrual nisus. *Passive* engorgement is observed as a consequence of labour, and of abdominal congestions. The local and general reaction in this variety is less obvious; the colour of the cervix is bluish instead of vividly red as in active congestion. *Mechanical* engorgement resembles the latter, it is caused by interruption to the uterine circulation, as by tumours or displacement of the organ itself.

The second variety of engorgement is inflammatory, being a step beyond that of active congestion. It may be produced by the same causes.

The hypertrophic engorgement is the consequence of prolonged irritation or chronic inflammation, or by deposit of additional tissue, either simple or heteromorphous. It may be of various consistence, according to the nature of the deposit and may induce certain secondary lesions as ulceration, granulations &c., The different diatheses as the scrofulous and rheumatic, as well as the syphilitic cachexia, may affect the uterus, and induce the variety of engorgement placed under this section.

GERMANY.

Skoda's Therapeutics.

Skoda is, as our readers are aware, an Austrian physician of extended repute; his mode of treating certain diseases may therefore prove interesting. It may be premised that his pharmacopœia is very limited; he swears by quinine, Dover's powder, and nitrate of silver; everything else he discards, or uses in a secondary sense. We extract from the *Gazette Mèdicale de Strasbourg* the following:—

In *pneumonia* he maintains that tartar emetic has no special action, and is useful only as an emetic when the bronchial tubes are clogged with secretion. In two severe cases of double pneumonia noticed by the narrator his treatment was bichloride of mercury; this he gave, without conviction of its utility, in doses of a quarter of a grain every four hours; one grain of Dover's powder at the same interval; and opium at night, if the patient was sleepless. The duration of his treatment was twenty-eight days. He never uses blistering.

In *pleurisy* he depends on digitalis. No blistering or cupping; occasional doses of Dover's powder.

In *typhus* he is guided by the symptoms. Mild purgatives if required, Dover's powder, and cold to the head.

Purpura is successfully treated by yeast.

Acute rheumatism is treated on the *methode expectante.* Dover's powder is generally the only medicine given.

So also in bronchitis Dover's powder is the chief medicine, either alone or combined with ipecacuanha.

Condition of the Internal Ear in Typhous Patients.

All writers on typhus fever have noticed the ringing of the ears and deafness which almost invariably accompany severe cases of that disease, and most physicians are disposed to regard these symptoms as nervous. M. Passavant, (*Zeitschrift für Rat. Medizin.,*) on the other hand, has examined the internal ear in a great number of patients cut off by typhus fever, and he has always found certain pathological lesions corresponding to the symptoms observed during life. The petrous portion of the temporal bone is congested, and the congestion extends to the internal parts, except those of most solidity. The transparency of the tympanum has disappeared; the membrane is thickened, red, and its epithelium peels off with great readiness.

This injection of the membrana tympani extends some way along the external auditory canal, and in some cases small spots of ecchymosis are found between the injected vessels. The cavity of the tympanum contains a thick viscid mucus, which is also found in the Eustachian tube, and in the cells of the mastoid process. The mucous lining of the middle ear is congested likewise, of a rose or bluish red colour. The labyrinth does not present any constant alteration, though some points of injection are occasionally observed. M. Passavant has not found the above described lesions in bodies of persons cut off by other diseases, not even in cases of inflammation of the ear. He therefore regards them as peculiar to typhus fever.—*Medical Times.*

Absence of the Sternum in a Child aged Eleven Years.

An instance of this rare deformity is related in the *Zeitschrift für die Gesammte Médécin.*, by Dr. Louis Benjamin. The sternum was replaced by two long narrow cartilaginous bands, commencing at the clavicle, and extending to the level of the seventh pair of ribs. Between the two bands was a space occupied solely by the soft parts, and which was perceptibly elevated at each systole of the heart. The child's health was remarkably good, and the respiratory functions were performed as in health.

General Retrospect.

PRACTICAL MEDICINE AND PATHOLOGY.

On the Pathology of Cerebral Softenings, as elucidated by the Microscope.—By Dr. Hughes Bennett.

[The nature of cerebral softening has been much disputed, a difficulty always existing as to their dependence on inflammatory action, or on a process analogous to senile gangrene. The following remarks are calculated to throw light on this obscure subject. Dr. Bennett says:—]

From a careful analysis of thirty-two cases of softening of the nervous centres, which were published in 1842-3, it may be concluded that two varieties of softening undoubtedly occur. In the one, the products of inflammatory exudation may be detected; in the other, these are not present. It is necessary to determine, with exactitude, the distinguishing characters of these two kinds of softening, which may be denominated inflammatory and non-inflammatory softenings.

Inflammatory softening always contains numerous granules and granular corpuscles, which are more numerous according to the degree of softening. The nervous tubes and normal structures are always, when the softening is great, more or less broken up. The nature of inflammatory softening of the brain, like all such lesions, depends upon the exudation of blood plasma, the development of granular corpuscles, and the subsequent breaking down of the latter.

If chronic, it may be considered a fatty degeneration of the brain. When recent, the serum poured out also assists in producing the softening.

In non-inflammatory softening, on the other hand, we find the cylindrical and varicose tubes of the part are rendered more soft and easily separable from each other. They have more or less lost their natural firmness and consistence, are readily torn across, the varicosities are easily enlarged by pressure, and, when separated or broken off, assume a globular form. The tubes also are more or less broken into fragments, and no exudation granules, masses, or granular corpuscles are to be detected.

The nature of non-inflammatory softening varies according to circumstances. It would seem to arise from four causes:—1st. From mechanical violence in exposing the nervous centres. 2nd. From a mechanical breaking up of the nervous tissue, by hæmorrhagic extravasations, whether in mass or when infiltrated in small isolated points, constitutiug capillary apoplexy. 3rd. From the mere imbibition of effused serum, which loosens the connection between the nervous tubes, and diminishes the consistence of the nervous tissue. 4th. From the process of putrefaction.

As regards the difference supposed by some to exist between the softening in adults and that in more aged persons, the author fully agrees with M. Durand-Fardel, when he says:—"Cerebral ramollissement is the same malady in old persons as in other adults; that it presents no other differences than the modifications which a variation in age always produces, connected only with the form, and not with the nature, of the lesion."

As for the opinion that softening of the brain is a lesion *sui generis*, due to diminution of nutrition, to gangrene, or obstruction of arteries, the author's observations has convinced him, that all such explanations are hypothetical in the highest degree, and have no real existence.

The cases which the author has recorded also indicate that different symptoms were present in such cases as were inflammatory, and in such as were non-inflammatory. Thus, in twenty-four cases carefully examined and analyzed, in which cerebral softening was observed, granular corpuscles were present in eighteen, whilst in six no traces of these bodies could be found. On analyzing the symptoms of these cases, we shall find a marked difference between those accompanying the one lesion or the other. Thus in the cases where *only* inflammatory softening was present, well-marked symptoms invariably existed, such as loss of consciousness, preceded or followed by dulness of intellect, contraction, and rigidity of the extremities, or paralysis. On the other hand, in the six cases of non-inflammatory softening, there was no paralysis or contraction, and no dulness or disturbance of the intellect. Again, in the four cases were both lesions were present, symptoms could always be observed in the sides opposite the inflammatory softening, while none existed opposite the non-inflammatory. An analysis of these twenty-four cases, therefore, leads to the conclusion, that the two kinds of softening are alike distinguishable, both by

their intimate structure, and by the symptoms accompanying them during life.—*Edinburgh Monthly Journ.*

MEDICINE.

On Coup de Soleil.—By Drs. Pepper and Condie.

Dr. Pepper believes that very erroneous notions respecting the nature of this affection prevail. Twenty patients have been admitted on account of it into the Philadelphia Hospital in seven years, of whom seven recovered, ten died, and three continued to suffer from chronic disease of the brain,—all these persons having been bled prior to admission. The prominent symptoms are violent convulsions, with muscular tremors in the intervals; a small, thready, irregular pulse, and dilated pupil. He has of late had the opportunity of witnessing four autopsies (from six to eight hours after death), at which there was found no congestion or other unusual appearance of the brain; but in all the heart was pallid, flaccid, and softened, though the other muscles were florid and firm. Its lining membrane (and that of the blood-vessels) was of a dark purple colour; its cavities contained little blood, and no coagulum. Similar appearances are described by Louis as occurring in typhoid fever that proves rapidly fatal. Apoplexy may occasionally, as it is too generally supposed to do, result from insolation; but the cases usually met with in hot summers bear no resemblance to it, and require stimuli instead of depletion. In all the fatal cases Dr. Pepper has met with, death occurred in six hours, and in the others recovery was slow, the mind continuing long in a confused state, and the case sometimes passing into one of insanity. The accident usually occurs to persons laboriously employed, while exposed to the sun's rays. Muscular exertion and excessive heat combine to stimulate the heart to morbid activity; copious perspiration and fatigue ensue; the organ becomes exhausted, and a passive congestion of the capillaries of the body occurs. It is a disease of nervous exhaustion, to be carefully distinguished from the cerebral congestion occasionally arising from the same cause. Of five cases treated by stimuli, three recovered and two died.

Dr. Condie observed, that the cases thus described are of common occurrence during hot summers, in persons engaged in laborious occupations, while exposed to the sun, and especially in those of intemperate habits. There is, however, another class of cases due to the same cause, in which the head, and often the entire surface, is intensely hot, the eyes are injected, the pupils contracted, the pulse small, quick, and corded, and the tongue red and dry. Such patients are delirious, morose, or constantly agitated; and if the acute meningitis, upon which these symptoms depend, is not treated by depletion, they die comatose.—*American Journal of Medical Science*, and *British and Foreign Medico-Chirurg. Review.*

Traumatic Tetanus; Treatment by Mercury; Recovery. By Dr. Elliot, West Indies.

A negress ran a piece of bamboo into the foot, on the 20th of Nov., 1850. Tetanic symptoms appeared on the 2nd of December. Was seen by the author on the 7th; she was then labouring under tetanus in an aggravated degree. She took powders every four hours, containing eight grains of quinine, with one scruple of calomel. On the 10th, ptyalism commenced, and on the 12th it was profuse. Next day the spasm had ceased.

[It is not easy to say in this case whether or not the *post hoc* was the *propter hoc*, most cases of tetanus which do not die before the 5th day, recover under various modes of treatment. The Hippocratic aphorism has been confirmed by modern observation.—Ed. P. J.]

SURGERY.

Communication of Gonorrhœa independently of Sexual Intercourse.—By Dr. Burke Ryan.

A case of considerable importance in a medico-legal, as well as moral point of view, was mentioned by Dr. Ryan, at a recent meeting of the Medical Society of London. Dr. Ryan was called to examine two children (sisters) labouring under a profuse purulent discharge, of a fortnight's duration in the elder, nine days in the younger. There was great inflammation of the parts in both. The explanation was, that a servant girl, labouring under profuse gonorrhœal discharge, as the mother of the child saw by her linen, was observed washing herself in the same vessel used for washing the children, and using the same sponge to her private parts as was used for them.

Had there been but one child, Dr. Ryan remarked, he might have passed it over as an ordinary, yet aggravated, case of vaginal discharge in a child; but as there were two consecutively affected sisters, of this tender age, with the infection's cause so easily traceable, he thought it worthy of record, and endeavoured to make it as plain as possible by further inquiry. He therefore saw the young woman. She had gonorrhœa, under which she had laboured during the last two months, using no means for curing it. She said she *did* use the children's sponge, as mentioned, but thought it more probable that the eldest child having sat upon the same vessel as herself, to pass water, was thus infected, and that the second took it from the sponge used for both. Some of the discharge was taken from *each of the three*, and the valuable assistance of Mr. Quekett sought for. He examined them under a magnifying power of 500 diameters. In that from the children there was scarcely anything but pus globules, thick, and well-defined. The discharge from the young woman, in whom the disease had been wearing itself out during two months, was of a more sanious character. There was epithelium in abundance; a few mucous, and also pus globules, diffused, but occasionally more aggregated.

Mr. B. Ryan remarked on the paucity of well-recorded cases of this nature given by elementary writers. Indeed, some of our best authors say that gonorrhœa is communicated by impure connection, and there leave the matter. Beck, speaking of vaginal discharges in children, where strong suspicions were entertained by a third party, of the discharge being gonorrhœal

bestows not the least attention in pointing out how the disease may be contracted in the manner above related, and how, consequently, undeserved suspicion may attach to an innocent person, to be followed, perhaps, as heretofore, by punishment. And Taylor, in giving, as one of the four sources of evidence of rape, the existence of gonorrhœa, adds shortly after:—"If the child be labouring under syphilis or gonorrhœa, this is positive evidence of impure intercourse either with the ravisher or some other person."—*Medical Gazette*, April 25, 1851.

Obstruction of the Bowels from Swallowing a Leaden Bullet.—By Dr. CUMMING.

The following case occurred in the garrison at Vizagapatam:—A boy, aged 11, two days after swallowing a bullet, complained of pain a little below and to the left of the umbilicus. In the hope of expelling the bullet, castor oil, with a few drops of laudanum, were prescribed, and leeches were applied; next morning, although the bowels were relieved, the pain was increased. The oil was repeated, with the effect of again moving the bowels, but without further benefit. In two days the pain shifted to midway between the umbilicus and pubis, showing that the bullet had moved lower down, and slight fever appeared. Obstinate constipation now ensued, and for three days resisted the most powerful purgatives. There was now also irritability of the stomach, and in two days more symptoms of collapse set in, with cramps, so as to give rise to suspicion of lead poisoning. Sulphate of soda was therefore given in solution for two days, seemingly without benefit. Under the idea that the retention of the bullet might be caused by the impaction of hardened fæces below, the author passed O'Beirne's tube, and by injection obtained copious scybalous evacuations, but the bullet could not be found. This plan was repeated with the same effect, and from this time his recovery commenced. The foreign body was never found.—*Edinburgh Monthly Journal*, April, 1851.

MIDWIFERY.

Successful Case of Transfusion.—By G. MASFEN, Esq.

A female, aged 38, was seized with hæmorrhage antecedent to abortion at the second month, which was treated in the usual way, but without effect. The fœtus was expelled, without cessation of the bleeding, which continued until the patient became *in extremis*. It being now the opinion that transfusion offered the only prospect of life, the author performed the operation. As the operation proceeded, consciousness was roused, and the pulse became perceptible, but these favourable signs disappeared at the end of half an hour. Three ounces more blood being injected, a rally again occurred, and again the patient lapsed into insensibility. A third injection of the same quantity produced more permanent benefit, and the pulse gradually gained power, and the patient became fully conscious. The stomach, however, rejected everything. Next day, six A.M., the pulse was 150, and very much increased in strength; the tongue dark-brown, hard, and dry. Ordered three drops of creosote, in form of a pill. She vomited almost immediately after taking it, but did not throw up the pill, which from that time appeared to allay the sickness. She then took a table-spoonful of brandy-mixture every hour. In the evening she still complained of thirst, and was ordered the following mixture:—Sesquicarbonate of soda, two and a half drachms; sesquicarbonate of ammonia, half a drachm; compound tincture of cardamoms, two drachms; oil of lemon, six drops; distilled water to six ounces. Two table-spoonfuls to be taken every three or four hours in a state of effervescence, with twelve grains of citric acid. There was great extravasation of blood for six or eight inches above and below the elbow in both arms, probably the effect of the injection. Ordered warm-water dressing. From this time the recovery was much expedited by the medicinal action of iron.—*Lancet*, April 19.

Correspondence.

MANCHESTER MEDICO-ETHICAL ASSOCIATION.

To the Editor of the Provincial Medical and Surgical Journal.

SIR,—We are instructed by the Committee of the Manchester Medico-Ethical Association to forward to you the enclosed correspondence for publication in the columns of the *Provincial Medical and Surgical Journal*. We are further directed to state, that the plan developed in the memorial of the Committee, was suggested with the view of superseding the necessity for prosecution, but that its signal failure leaves them no alternative but to proceed actively with that project.

We are, Sir, your obedient servants,

JOHN AIKENHEAD,
W. C. WILLIAMSON, } Hon. Secs.

Manchester, May 19, 1851.

To the Registrar and Lecturers of the Pine Street (and Chatham Street) School of Medicine.

Gentlemen,—At the last annual meeting of the Manchester Medico-Ethical Association, held Jan. 15, 1851, it was unanimously resolved:—"That the important proposal of submitting to the Medical Officers of the Hospital, and Medical Schools of this town, the propriety of not allowing persons practising whilst unqualified, to attend the practice and lectures of those institutions, be submitted to the early consideration of the Committee, that they may take the necessary steps in the matter."

Increasing and wide-spread complaints are continually being made concerning the injurious effects upon the profession of students practising medicine with a view to emolument during their pupilage and attendance on lectures; and the committee of this Association believe that the complaints are well founded, and that the dissatisfaction engendered is just and reasonable.

Appointed to conserve the honour and interests of

the profession, the Committee believe that you as the Registrar of the Pine Street (Chatham Street) School of Medicine, will, with your colleagues, take this subject into your serious consideration.

It is, of course, well-known to you that a considerable number of students entering the schools of late years are at the time druggists, and practising medicine as a profession. The committee believe that many of these are actuated by the honourable and praiseworthy motive of qualifying themselves for examination, and of becoming legal and respectable practitioners. But the committee submit that while this should, to a certain extent, be encouraged, it should not be done at the expense, or to the detriment of the profession.

It is, therefore, respectfully suggested that, while every encouragement is given to the honourable and aspiring druggist, he should be required, on entering his curriculum of study, to confine himself strictly within the limits of his calling, and to pledge himself not to practise medicine. If this should occasionally be deemed a hardship, it will be an initiation into honourable and professional conduct, and even conducive to his future interests, when he finds that upon entering into practice legally, he is in turn equally protected.

So far the Committee speak of those who are actuated by the most commendable motives. It is a fact well known, however, that many enter the schools for the purpose of direct emolument. Certificates of lectures are exhibited as licenses and diplomas, and the ignorant are led to believe that their possessors are fully-qualified medical men. In some districts this has been attended with results which the lecturers of your school would be pained to learn; and the Committee feel assured that these are consequences of provincial medical schools which their spirited founders never contemplated, and would willingly remove. Of course it is not for a moment considered that the refusal of a pupil who would not pledge himself, or of a certificate to one who had violated his agreement, could be retrospective; but it is considered that it might with honour and advantage be carried out with all new students, and prospectively even with those who have only entered to single courses of lectures, or to a single session.

The Committee beg further to state, that this evil which they deplore and seek to remedy, has already received the attention of the Leeds School of Medicine, which has adopted a course somewhat similar to that now pressed upon your consideration.

In conclusion, the Committee desire that the subject may be taken up by the several institutions named in the resolution above referred to, in the spirit which has actuated the Medico-Ethical Association, believing that whilst it will be grateful to the profession generally, it will be more especially calculated to exalt the character and position of those institutions, by giving their alumni a higher character, and themselves an increasing usefulness and permanency.

Signed on behalf of the Medico-Ethical Association.

James Lomax Bardsley, M.D., President.
John Aikenhead, M.D., } Hon. Secs.
W. C. Williamson. }

Manchester, March 18, 1851.

A memorial, similar in effect to the above, was also addressed to the Medical Board of the Royal Infirmary.

To the President and Honorary Secretaries of the Medico-Ethical Association.

Gentlemen,—I have been requested to transmit to you the following resolution which was passed at a meeting of the Lecturers of the Manchester Royal School of Medicine and Surgery, held on March 28, 1851.

I am, Gentlemen,
Your obedient Servant,
R. T. Hunt, Hon. Sec.

Manchester, March 31, 1851.

Resolved—"That the receipt of a communication from the President and Honorary Secretaries of the Manchester Medico-Ethical Association, addressed to the Registrar and Lecturers of the Pine Street School of Medicine, and relating to the students of the school, be acknowledged."

To the President and Honorary Secretaries of the Medico-Ethical Society.

Gentlemen,—At the last meeting of the Lecturers of the Chatham Street School of Medicine, I presented your memorial, relating to the exaction of a pledge from the students on entering to the courses of lectures delivered in this place. After maturely considering your suggestion, the following sentiment was carried by a majority of those present at the meeting:—"The Lecturers of the Chatham Street School of Medicine beg to acknowledge the receipt of the memorial of the Medico-Ethical Society, and regret equally with them the faults alluded to; but they are of opinion that they would not be justified in pursuing the course pointed out to them by the Society.

I have the honor to remain, Gentlemen,
Yours very respectfully,
J. H. Watts.

Chatham Street School of Medicine,
April 11, 1851.

To the President of the Medico-Ethical Society.

Sir,—By order of the Medical Board I beg leave to send you extracts from the minutes of proceedings passed at the meeting held this morning.

I am, most respectfully, Sir,
Your obedient Servant,
J. Woodward, Secretary.

Royal Infirmary, Dispensary, &c.,
Manchester, April 24, 1851.

"Read a communication from the Medico-Ethical Society."

Resolved—"That the control of the Medical Board is limited to the conduct of the pupils within the wards of the Hospital, and they decline to entertain the proposal of the Medico-Ethical Society now submitted to them, and that a copy of this resolution be forwarded to the Medico-Ethical Society."

ON THE EXAMINATIONS AT THE COLLEGE AND HALL.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—Will you allow me a small space in your journal to correct an error into which your Sexagenarian correspondent has fallen, in common with numerous others.

Your correspondent asserts it as a fact, that the examination at "the Hall" is of a much "more stringent character," and is looked upon with more "apprehension, and a sense of dread," than that at the College of Surgeons.

There is not a more erroneous notion in existence in the profession. I have lately passed the examination at both, and also know the prevalent opinion amongst students, with regard to the relative severity of the two. I studied at one of the largest hospital schools in London, and I know that the students there generally look upon the examination at the College as the more stringent, and also as requiring more time to prepare for it. *A greater number of men are plucked at the College than at the Hall.* A year ago I passed the Hall; the same evening thirteen candidates presented themselves for examination, and *all passed*, and I know that for five examination days succeeding not a single candidate was rejected, although at each Court from eight to fourteen presented themselves. A few weeks afterwards I passed the College; fourteen candidates presented themselves, and *five were plucked*, and for several examination-days before and after that time from three to six men were rejected each time. These statements are *facts*, not speculations, and occurred about the same time that every examined candidate at the Hall passed; and I have no doubt but that during the whole year the number of rejected candidates would be in about the same proportion. Then, how can the examination at the Hall be the more stringent?

The College examiners never hold a court when there are less than twelve candidates to be examined, and sometimes there are sixteen or twenty, yet how seldom do we see twelve or sixteen names down in the pass-list for a single day; I have seen as few as *four*, so that *no less than eight* must have been rejected. I have no hesitation in stating, that so many are never rejected at the Hall. I cannot see how the two examinations can be compared; one requires a sound and extensive knowledge of but a few subjects, the other a mere superficial acquaintance with many; and the examiners themselves have not sufficient knowledge to go very deeply into any subject. One of the examiners told me that ammonia was formed by the *decomposition* of hydrogen and nitrogen!! Fancy two *simple elements* being *decomposed!* If the examiners are no better informed than this one, what is the examination worth? None of them are men known to science, or even to their own profession, except two or three have the reputation of being retired grinders. The examiners at the College are men thoroughly competent to test the candidates in the subjects they profess to examine in, viz., anatomy, physiology, and surgery. Many "Sexagenarians" have fallen into a great mistake when they suppose that students dread the Hall more than the College: the reverse is *almost always* the fact, and for a very obvious reason, it requires much less time and application to get a smattering knowledge of the multifarious subjects required by the wise sages at the Hall than it does to get a thorough knowledge of the three subjects for the College. The most idle and dissipated student can, by a few week's "grinding," acquire a sufficient acquaintance with the subjects for the Hall, while I doubt if he can know much anatomy without dissection.

But, without stating any more reasons, I think the facts I have given, viz., the proportion of rejected candidates at the two boards, are conclusive. I do not think the examinations either at the Hall or College are worthy of the name,—neither of them test the candidate's knowledge of the most ordinary cases occurring in practice. The examination at the University of London is the only one which can with propriety be called such.

One word with regard to the student having a "competent acquaintance with the French, German, and Italian languages." I heard a most distinguished physician—himself no mean scholar, and certainly the best clinical teacher in London—make the remark, that "a Frenchman would easily write a work in three folio volumes on a *flea's leg*." If this be the fact, would it not be a great waste of time to wade through so much verbiage for so trifling an object?

I am, Sir,

Your most obedient servant,

S.

May 19, 1851.

P.S. I have enclosed my card.

Medical Intelligence.

RESOLUTIONS UNANIMOUSLY ADOPTED BY THE ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, REGARDING PRACTITIONERS OF HOMŒOPATHY.

At Edinburgh, and within the College Hall there, the 9th day of May, 1851, an Extraordinary Meeting of the Royal College was held, pursuant to a resolution agreed to at the last Quarterly Meeting, and of which Extraordinary Meeting due notice was given. The President in the Chair.

The following resolutions were moved, seconded, and unanimously agreed to:—

1. That the Royal College of Physicians of Edinburgh did, several years ago, publicly express its opinion of homœopathy and homœopathic practitioners, by peremptorily declining to admit into its body a candidate for its Fellowship who belonged to that denomination; and, consequently, that no Fellow of the College can possibly be ignorant of the light in which all those who practice homœopathy are regarded by the College.
2. The College regrets that, notwithstanding this decided expression of its opinion, more than one of

its Fellows, after being admitted in a different character, have endangered the reputation of the College, by becoming homœopathic practitioners; and the College expresses an earnest hope that these Fellows, seeing they have thus virtually separated themselves from the College, will spontaneously sever their further connection with an Institution which repudiates them, and from which they can derive as merely nominal Fellows, nothing else than a false position and a spurious credit.

3. The College feels the more bound thus to express its opinion, seeing that those Fellows who have become homœopathists, and any other medical practitioners who follow homœopathy, must necessarily be aliens to the other Fellows, and to the profession at large; inasmuch as no Fellow of this College, or any other physician can, by any possibility, without derogating from his own honour, and from the honour of the profession, meet practitioners of homœopathy in consultation, or co-operate with them in the other common duties of professional life.

4. That, although the College has not thought it expedient hitherto to take any active steps for disclaiming those Fellows who have become homœopathic practitioners subsequently to their admission to the College, nevertheless, since it has the power of dealing summarily with those who act in a manner so unbecoming the character of a physician, it reserves its right to exercise that power when it shall be so advised.

Signed in name, and by authority, of the College,

J. Y. SIMPSON, President.

BRITISH MEDICAL FUND.

A meeting of the medical gentlemen of Worcester and the neighbourhood was held in the Council Room of the Worcestershire Natural History Society, on Monday, the 12th instant, for the purpose of receiving from Mr. Hawtayne, the Secretary of the the "British Medical Fund," a statement in reference to the objects of that institution. Amongst the gentlemen present were Dr. Malden, Messrs. Carden, J. H. Walsh, T. Walsh, Shelton, Jones, Davis, Jeffery, Busigny of Ombersley, &c. Dr. Malden was requested to take the chair, and having opened the proceedings by some lengthened and appropriate observations on the object of the meeting and on the advantages calculated to result from such an institution as that they were now called upon to support, the secretary at once proceeded to a detail of the various objects and benefits contemplated by the Society, and expressed his gratification that throughout his provincial visitation it had hitherto met with the warmest encouragement and support.

Several questions having been put to the secretary and answered satisfactorily, the following resolutions were proposed and carried unanimously:—

1st. "That this meeting highly approves of the principles and objects of the 'British Medical Fund,' and strongly recommends the Society to the profession at large for encouragement and support."

2nd. "That the best thanks of this meeting and of the profession generally, are due to Dr. Forbes and the Directors of the British Medical Fund, for their zealous and indefatigable exertions in establishing the institution."

3rd. "That the thanks of this meeting be given to Mr. Hawtayne, the Secretary of the British Medical Fund, for his satisfactory explanation of the nature of the Society."

A vote of thanks having been offered to Dr. Malden, for his very able and courteous conduct in the chair and for his kindness in presiding on this occasion the meeting separated.

We understand similar meetings are being held in various towns throughout the kingdom, in favour of this praiseworthy Institution.

EXAMINATIONS AT ABERDEEN.

A correspondent, having obtained the degree of M.D. at the last examination at King's College, Aberdeen, requests us to publish the following list of the chief subjects included in the examination to which he was subjected, as some guide to those who may go up hereafter for that dignity. He mentions, however, that the subjects of the examination of each candidate were different.

First Examiner: General physiology of secretion and nutrition; minute anatomy of liver; composition of bile; use in digestion; physiology of digestion; anatomy of intestinal canal; minute anatomy of kidney; secretion of urine; urinary deposits; different diatheses; composition of urea and uric acid; effects of urea in circulation; minute anatomy of testis, its secretion; anatomy of male organs of generation; physiology of respiration; asphyxia; respiration in lower animals; chemical condition of blood, arterial and venous, healthy and diseased; effect of tying renal vein, portal vein; fœtal circulation; placental circulation; origin of cerebral nerves; eighth pair; branches, distribution, &c.

Second Examiner: Differences between scarlatina and measles; symptoms; pathology; treatment of different forms of each; sequelæ of each, and treatment; diseased condition of urine; croup; objections to tracheotomy in it; spasmodic croup; peritonitis; acute and puerperal phlebitis; phlegmasia dolens; puerperal mania; erysipelas, all its forms and treatment; delirium tremens; cerebritis and meningitis; gaol fever; pleuritis and pneumonia; their stethoscopic signs and different stages, &c.

Third Examiner: Surgical diseases of head, and operations for injuries, especially fractures and concussion, dislocation and fractures; erysipelas after injuries; abscess; gangrene, &c.

Fourth Examiner: The preparations of iron in the Pharmacopœia; doses, strength, uses, &c.; mode of preparing the principal of them; preparations of mercury in Pharmacopœia; doses, uses, &c.; mode of preparing calomel and bichloride; tests for latter; effects and antidotes as a poison; treatment; ditto ditto for arsenic; chemistry of hydracids, hydrocarbons, hydrates, compounds of chlorine with oxygen, &c.; writing prescriptions in Latin, abbreviations, &c.—*Lancet.*

APOTHECARIES' HALL.

The Court of Examiners have resolved:—

"1. That a preliminary examination for junior students of the medical profession would be desirable, as an important auxiliary to their subsequent professional studies.

"2. That such examination should comprise an inquiry into the student's knowledge of the Latin and Greek languages, and of the elements of mathematics.

"3. That students should be admissible to such examination at any period from the date of their apprenticeship to the completion of the first winter session of their curriculum.

"4. That such examination should, in the first instance, include the following subjects, viz.:—

"1. The first book of Virgil's Æneid and Cicero's Oration for Milo.

"2. The Greek Testament to the end of the Acts of the Apostles; or, the first book of Xenophon's Anabasis, at the option of the candidate.

"3. Algebra, as far as Simple Equations.

"4. The first book of Euclid's Elements.

"5. That the student who passes this examination satisfactorily should not be subject to any subsequent examination in Latin, except the Pharmacopœia Londinensis and Prescriptions.

"6. That students who have not passed this examination should for the present be allowed, as heretofore, to undergo the preliminary examination in Celsus and Gregory, after they have completed two winter sessions of their medical studies."

DEATH FROM CHLOROFORM.

A death from the effects of chloroform, administered with a view to its anæsthetic action, is reported from the Stepney Union-house. The unfortunate man was a baker. The dose given of the chloroform was small; half a drachm being employed first, and, that failing to produce any action, another half drachm was used, and the fatal result occurred. The surgeon who administered it said that he had examined the man and found nothing to prohibit its use. He attributed the death to a peculiar idiosyncrasy, rendering the man very susceptible of the action of the chloroform; that is to say, he did not know in what way to account for it. The manner in which the chloroform was administered is not mentioned.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted members on the 9th instant:—Francis Trevelyan Buckland, Deanery, Westminster; Alfred Carpenter, Rothwell, Northamptonshire; Wm. Tait Carr, Aberdeen; Frederick James Chaldecott, Dorking, Surrey; Fohn Fountain, Cowley, Uxbridge, Middlesex; Albert William Hanford, Nottingham; Ebenezer Moore, Islington; Henry Power, London; Henry Simpson, Chester; Thomas Henry Cornelius, Vauxhall Road, Pimlico; Edward George Wake, Hull; William Warwick, Belfast; Richard Wellings, Ravenstone, Leicestershire; John Wilde, Islington; Edwin Wilson, Hyde, Cheshire.

Gentlemen admitted members on the 16th instant:—Lancelot Armstrong, Camberwell; Thomas Britton, York; Geo. Brennan, Cork; John Davis, Sunderland; Nevill Jackson, Stamford, Lincolnshire; Edward Lang, Dublin; Edward Ralfs, Tunbridge, Kent; Jacobus Silverman, Middlesex Place, Paddington; Thomas White, Chester. Frederick Wm. Wilders, Chesterton, Huntingdonshire.

SOCIETY OF APOTHECARIES.

The following gentlemen were admitted members on May 8th, 1851;—Thos. Bickerton, Liverpool; Henry George, Kirton Lindsey; William Edward Hayman, Abingdon, Berks; Thomas Lancaster, Badcliffe Bridge; John Davies Weaver, Chester.

The following gentlemen were also admitted members on the 15th instant:—Thomas Dicklinson, Chelsea; Joseph Earle; James Gardner, Worthing; David Johnson, Horsmonden, Kent; George Stunt; Stephen Chapman Townsend, Crediton, Devon.

OBITUARY.

May 16th, at York Terrace, Regent's Park, Charles Shillito, M.D., formerly of the West Essex Militia; and late of Putney, aged 69.

May 17th, Dr. Edward Clark Baker, late of Walcot Terrace, aged 48, of consumption.

BOOKS RECEIVED FOR REVIEW.

Practical Remarks on the Treatment of Aneurism by Compression. By Joseph Tuffnell, M.R.S.A., &c., &c. Dublin: Fannin and Co. London: J. Churchill, 1851. pp. 154.

On the Structure of the Membrana Tympani of the Human Ear. By Joseph Toynbee, F.R.S., &c., &. London, 1851. 4to, pp. 10.

An Inaugural Essay on Zoo-Adynamia. By George J. Ziegler, M.D. Philadelphia, 1850.

London Journal of Medicine—May, 1851.

Monthly Journal of Medical Science—May, 1851.

On Excision of the Enlarged Tonsil, and its consequences in cases of Deafness. By W. Harvey, M.R.C.S., &c. London: H. Renshaw. 1850. pp. 121.

On the Mode of Origin, and Propagation of the Epidemic Cholera in Huddersfield and its neighbourhood in the autumn of 1849. By John Taylor, M.D., London, &c., &c, London: Tyler. 1851.

Dublin Quarterly Journal—May, 1851.

The Medical Examiner, Philadelphia—March and April, 1851.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

WEST SOMERSET BRANCH.

The annual meeting of this Branch will be held at the Squirrel Hotel, Wellington, on Wednesday, June 4th proximo. W. Trevor, Esq., President; S. F. Bridge, Esq., President-elect. The chair will be taken at two o'clock P.M.

FRANCIS HENRY WOODFORDE,
Secretary.

Taunton, May 22, 1851.

TO CORRESPONDENTS.

Communications have been received from Dr. Cotton, Mr. Clapp, Mr. Green, Mr. Duke, Mr. Propert, Dr. Radford, Mr. Beard, Mr. Deans, Mr. Godfrey.

Doubtful.—There can be no doubt that the gentleman referred to is capable of procreation. There are many cases proving the fact both in the domestic animals and in man. We are ourselves aware of two cases in which children have been got after the removal of one testicle.

It is requested that all letters and communications connected with the *Editorial department* be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho.

CLINICAL LECTURES

ON THE

PRACTICE OF PHYSIC,

DELIVERED IN THE

THEATRE OF QUEEN'S COLLEGE, BIRMINGHAM.

By DAVID NELSON, M.D.,

Physician to the Queen's Hospital, and Professor of Clinical Medicine, &c.

[Reported by MR. HENRY GREEN, Student.]

LECTURE V.

On the Morbid Conditions of the Heart and Circulating Tubes.

The morbid conditions of the heart are almost of equal importance to those of the head. In many cases death is instantaneous; in others the rise and progress of disease is more slow and insidious, yet not the less fatal; in all, even the slightest symptoms are to be gravely considered, as ultimately they may induce consequences of a serious kind, though not a matter of certainty or necessity. Before entering upon the different forms of disease to which it is subject I shall offer you a simple sketch of the organ itself in its natural state, divested of all unnecessary detail, only with a view to bring freshly before you its healthy, compared with its morbid, condition. The heart, then, as you are aware, is a hollow muscle, containing four distinct chambers, involuntary in its movements, yet possessed of fibres similar to those of a voluntary muscle. It is of a conical shape, enclosed within its bag or pericardium, and is attached by the fibrous expansion of its pericardium, as well as by the great blood-vessels, to the thorax behind, though in a manner that permits of very free motion. Its base, where all these blood-vessels enter or emerge, lies as nearly as possible under the centre of the sternum, while its apex points towards the left, and ought to impinge in its contraction at a spot about two inches below the left nipple and one inch to the right side thereof. The size of the organ may vary a little in different individuals without the presence of any disease; but there is a general healthy proportion which it bears to the body, a rude yet useful-enough approximation to which is expressed by saying that the heart ought to be about the size of its possessor's closed fist. Of the four chambers into which it is divided inside, the two auricles are the smaller and the two ventricles much the larger, to external appearance. The auricles, however, as being more passive, are furnished with very thin loose walls, whilst those of the ventricles, and especially that of the left, are thick and solid. The chambers of the right side are devoted to the purposes of the pulmonic part of the circulation, by receiving the returning venous blood and projecting it into the lungs for aëration, whilst those of the left are devoted to the purposes of the systemic part of the circulation, by receiving the aërated blood from the lungs and distributing it through the body at large. These combined portions act upon the principle of a double force-pump, as may be seen by tracing the course of the blood through them and watching their mode of operation. Thus we see, in the first place, that by means of the great systemic veins all the vitiated blood of the frame is poured into the right auricle by a continuous flow, without being shut up there by any perfect valve, the absence of which at this point conduces to safety; as in event of any stagnation in other parts of the heart there is no passing forward of the blood from this first chamber. There is a free natural passage backwards as well as forwards, though the partial closure of the Eustachian valve somewhat impedes the former motion, and the contractions of the auricles are so gentle that whilst they have no tendency to engorge with any vehemence the next chamber, neither do they produce any appreciable pulsation in the veins, which, when it exists, is owing to the regurgitation of blood during the more powerful action of the ventricle, when the auriculo-ventricular opening happens to be patent. But the auriculo-ventricular opening of the right side is naturally closed during the contraction of the ventricle, under the very act of this regurgitation; for the opening being surrounded by the three flat plates at the base of the auricle, to the edges of which are attached the tendons of the columnæ carneæ, or cross muscles of the ventricle, these, under the action of the columnæ carneæ and walls of the ventricle are so drawn up together that they constitute the complete valve called the tricuspid. Within this right ventricle, by means of its contraction and the intersection of its transverse fleshy columns, the varied returning fluids of the ordinary veins, the portal vessels, the lymphatics, and the chyle are all duly intermixed, and so propelled forwards to the lungs. For this purpose there is complete resistance to the regurgitation of blood, by the closure of the tricuspid valve, while the pulmonic semilunar valves are pushed forwards with ease, immediately clapping backwards as soon as the weight of the column above exceeds the force exerted from below. Having undergone a vivifying change in the lungs, the blood next returns to the left auricle by means of the four pulmonary veins, whose openings are even more patent than those of the systemic veins, and permit of free egress to the blood, whenever it is required. Again, however, we find the principle of the tricuspid valve repeated in that of the mitral valves, at the left auriculo-ventricular opening, and likewise the principle of the semilunar valves of the pulmonary artery repeated at the aorta. Such are the mechanical contrivances at the central organ of the circulation, which affords full means for its safety and efficiency. Strong as is the action of the heart, it ought not in a healthy person of moderate plumpness to be very apparent, except under excitement; nor if the lungs are sound ought it to give any dulness on percussion, except over two inches or so of the chest; and if emphysema exist there may be no dulness at all. Two sounds, however, ought always to be distinctly heard. The first, the more prolonged of the two, corresponding to the filling of the auricles and the emptying of the

ventricles, while the second corresponds to the flapping back of the semilunar valves. After these two sounds there is a pause of relaxation, equal in duration to that of the two sounds conjoined, the then contraction of the two auricles being apparently too gentle to elicit any appreciable noise. We talk of longer or shorter by comparison, for of course the longest is but very short in reality. Taking, for instance, a moderate pulse at 60 in the minute, and considering that 120 sounds are produced each minute, and that 240 would be produced but for the pauses, we find the longest sound of this slow pulse would be little more than a quarter of a moment. In a pulse of 120, very common under disease, it would be little more than an eighth; in one of 140, which is not uncommon, up to 160, which is rather uncommon, it would range from a ninth to a tenth of a moment. Such a view of the matter shows us very clearly to what a degree the ear must be trained and educated before it learns to discern with nicety any little alteration in their natural sounds; and points out with what assiduity a student should examine them on all possible occasions if he desire to compass their familiar acquaintance. As in most affections within the heart itself, evidence thereof will be sought for by an inquiry into the sounds elicited over the valves; it is a matter of great consequence to know their relative situation. Beginning with the first in the order of the circulation, we are to listen for the sounds of the tricuspid valve, a little to the right of the middle of the sternum, remembering, however, that we had better begin to listen at some distance from the spot, and so gradually approach nearer and nearer from different quarters in order to determine that they are loudest there; because all of them are so near each other, that if any of them happen to be very loud, it may be so propagated as to give room for mistakes. A murmer, if heard there with the first sound of the heart would prove regurgitation, and if with the second, some narrowing of the orifice. A secondary evidence of the regurgitation would be the jugular pulse, and an accompaniment of either condition would be a general tendency to venous congestion. With the like precautions we are to listen for murmurs from the next set of valves, viz., the pulmonic, over the centre of the sternum. These are very seldom diseased, and the murmers might be confused with those from the aortic valves immediately behind; but if they be from the pulmonics, they will be very superficial, and will be propagated most towards the left-side, in the course of the pulmonary artery; yet even in that case let it be recollected that any solid body in the aorta pressing through against the pulmonary artery and there causing a bulging of its side, may give rise to a rough sound in its course, even whilst quite healthy. This was illustrated in the case of Shaw, whose aortic valves were found after death incrusted with phosphatic concretions, which, by their size, pressed through on the pulmonary artery, narrowed its calibre, and produced a murmer in its course. The murmers of the mitral valve are to be searched for to the left of the sternum. If accompanying the first sound, they will indicate regurgitation, and if accompanying the second, a narrowing of the opening. Both would tend to produce an engorgement of the lungs. Those of the aortic valves are to be listened for in the same situation as the pulmonic, but they will be deeper seated, and heard most distinctly in the course of the aorta towards the right. If heard with the first sound they will prove a narrowing of the orifice, and if with the second, a regurgitation. In the former case, the pulse will be smaller than usual, and in the latter it will be jerking, or retrogressing, as it were, after the first bound. In either case the obstacle will be propagated backwards through the whole of the chambers, and will tend to induce an inclination to general congestion, and all the other consequences of an universally obstructed circulation. Such morbid murmurs may sometimes be produced by other circumstances than organic causes, as, for instance, an over liquidity of the blood, or its fibrinous condition producing clots in the heart; but these will not be so permanent and invariable as those that arise from organic changes. The tissues of the heart are a serous membrane on its inner surface, called the endocardium, the muscular substance of its walls, with the fibro-tendinous structures about its valves, and a serous pericardial lining outside. A large plexus of nerves, camposed chiefly of the ganglionic system, with branches of the pneumogastric, lie at its base, and a series of ganglia are found throughout its substance. The whole organ, as a body, lies within its loose bag, reflected back, as it were, from its base. This pericardium consists of a fibrous membrane outside, lined by a serous membrane, which is reflected upon the outer surface of the heart. The inner surface of this bag may become filled with serum, pus, or blood, and cause an extensive dulness, along with faint sounds and motions of the heart; or it may become partially glued by lymph to the opposite surface of the heart, and cause a friction-sound at each motion, or impede the motion to a great degree.

In directing our attention towards the heart, which should be done in every case, but especially in rheumatism, a few seconds will suffice to prove that its action and sounds are natural. If there be any irregularity, our next inquiries must be as regards pain or occasional palpitation, or whether its motions be quicker or slower, or more or less forcible than they should be. We must also observe whether the dulness on percussion be more extensive than usual, whether the apex impinges at the wrong point, and whether the sounds be of one morbid character or another, and where heard most distinctly. These observations as to its degree of irritability, its physical magnitude, and its motions and sounds, include the whole chain of investigation. To be expert at this requires long practice, but its acquisition is worth any amount of labour. All of these symptoms must proceed, either from irregularity in the supply of nervous power, or from anæmia, or hyperæmia, or some perversion of the nutritive fluids. I shall first take notice of those ailments connected with enervation, and which need not detain us long. The irritability may be so increased under natural or accidental debility, that certain convulsive motions, called palpitation, may

arise from time to time, due to some cause of irritation, either in the stomach, bowels, uterus, or brain. In such cases the very slightest deviation from a state of ease in body or mind, will cause the supervention of a fit of palpitation, without any organic disease of the heart whatsoever. In event of the blood being very thin, which it generally is under such circumstances, there may be heard during the fit a slight blowing sound over the valves; but that will disappear again as soon as the circulation is quieted. These simple palpitations, though very annoying, are not of much consequence in themselves, but they are important as evidences of the debilitated state of the general constitution, and of the tenuity of the blood. They are most frequently connected with dyspepsia and chlorosis, but will accompany any exhausting disease, such as phthisis, or any extensive loss of blood, or long course of starvation, or anxiety of mind. In every case we have to remove any discoverable cause of irritation, and invigorate the constitutional powers by means of nutrients, tonics, and sedatives. With this view we may have to use emmenagogues in the event of a suppression of the menses, mild purgatives, stomachic bitters, and antacids in case of dyspepsia, carbonate of iron if the paleness of anæmia be present, and cod-liver oil if the patient be excessively thin. It will also be right to calm the irritability of the system by such sedatives as act more directly on the heart, as hydrocyanic acid, or a belladonna plaster; yet, combined with a tonic, which may be the muriated tincture of iron or the carbonate, or Fowler's solution, or quinine, according to the conditions of other organs. Should the palpitation be chiefly traceable to mental emotions, then the tincture of castor oil will be found of much avail. But in every case the various appliances of a tonic regimen, must accompany the medicinal treatment, and open air recreation, bodily and mental employments short of fatigue and excitement, cold bathing, generous light diet, and a moderate allowance of wine or malt liquors, especially porter, should be enjoined.

As palpitation is a convulsive action of the heart, so cardialgia or purely nervous agony, is to be viewed as a spastic contraction of that organ in some of its fibres at least; so that they do not act in correct concert with one another. It may be very difficult to prove such an assertion by direct physical demonstration. Nevertheless, there is no reason to doubt that the fibres of the heart, may be affected by spasm, as well as those of the bowels; and reasoning from analogy, when we find pains of a like character in different parts of the body, we are entitled to attribute them to like causes. Much dispute arose on this subject when Lord George Bentinck died. Simply neuralgic pains may, perhaps, be distinguished from this affection; but I think there is little doubt that the very severe form of cardiac pain, called angina pectoris, is due, in its essential character of a pain, to some irregular and spasmodic action of the muscular fibre. The causes of this irregular action in that extreme case, may be the existence of a foreign body in the heart, such as a cancerous or osseous deposit, and shall be treated of under another head, but its distinctive definition is that of a spasmodic pain, so that angina pectoris is to be viewed as a simple symptom, and not as a distinct disease, any more than the pains of rheumatism, or the headache of fever. Adopting this doctrine it will be unnecessary to allude further to this affection at present, than to say, that while it is an attendant upon different organic changes in the structure of the heart, it is also known sometimes to display itself irrespective of any physical change; yet, as in either case, it comes as a sudden pang and so departs, it must be considered in the light of a spasm. Should organic disease appear to be the cause, our attention must be directed to that source of excitement; but if it appear as a simple spasm, then antispasmodics must be chiefly relied upon.

In contradistinction to either convulsion or spasm, there may also be a paralysis of the heart. If this be partial, there may only be a simple depression of the heart's action as in typhus or other adynamic fevers, or under the influence of medicinal doses of hydrocyanic acid, digitalis and the like, or at most, we may merely have that milder form of syncope from which people may readily rally under the application of smart stimulants. This condition, as now stated, may proceed from direct impressions on the the cardiac ganglia themselves, as we know, that by the law of specific determination, several poisons of different kinds may be directed in a special manner towards those centres, or it may arise from causes primarily acting on the brain, or the peripheral expansions, as already stated in the lecture upon affections of the nervous system. Each of these causes, if sufficiently sudden or powerful, may induce a complete and permanent paralysis of the heart, under the name of fatal syncope. Mental shocks, the poisons of cholera or hydrocyanic acid, extensive burns or scalds, all act after this manner if in sufficient force. Rapid and instantaneous as death is under such circumstances, there yet occurs in most cases, a sufficient interval for the heart to make one final effort to propel whatever blood may be in it at the moment. This is proved by the almost universal, yet not necessary fact, of the organ being found empty of blood after death by syncope; for it is obvious, that if the paralytic shock were sufficiently rapid, and took effect at the precise point when the chambers were filled with blood, all further motion would be for ever arrested, and the organ would be found to remain as it then had been, namely, gorged with blood. The emptiness is only owing to the fact, that the shock is very seldom so rapid as we here suppose it might, and certainly could, be. I beg to call your special attention to this mode of reasoning upon such subjects, because it has been through the non-perception of it that so many disputes have arisen upon this and other matters of a like kind, each disputant basing his assertion upon certain facts frequently observed by himself, and furnished to him by others, as contrasted with other facts, which he has never observed himself, nor had furnished to him, except in limited number. Upon this simply numerical comparison he may either doubt the existence of the latter altogether, or else receive them as exceptions

to a general rule. In the latter case he encumbers his mind with a number of crude dogmata, each requiring to be bolstered up by a long series of such exceptions, whereas a really fundamental principle of philosophy can admit of no exception whatsoever; and we may depend upon this that, whenever we meet with such exceptions we have not yet carried our generalizations sufficiently far. Applying this rule to the question before us, it can admit of no doubt that, in almost every case of death by syncope, the heart is deprived of blood, and in but a few instances has it been found gorged. Nevertheless, these two facts are not contradictory of one another, neither is the latter less positive in its nature, because it may be the rarer of the two; nor is it an exceptional departure from any principle such as is supposed to govern the more numerous body of facts; on the contrary, they are but exemplifications of one principle, according to the degree in which it may be applied. A shock or injury of some kind penetrates to the nerves of the heart, and paralysis ensues. If not very severe, effectual re-action may supervene, and life be restored; or an ineffectual re-action may take place, so that the organ may continue a few faint, and far-between motions for some time; or it may give but three, two, or one beat more. But the injury may also be so powerful, that no re-action whatever takes place, so that without one further effort the organ may be stilled at once and for ever, under which circumstances the arrest, as a question of time, may certainly occur either during systole or diastole, and therefore the absence or presence of blood becomes a mere matter of accident, in proof of which Dr. Christison relates a case of gorged heart after a death of this kind. I am thus particular in inculcating the relative position which these facts bear to one another, because the confusion of essential with accidental occurrences, not only in this question but in most others, has too often characterized the reasonings even of very eminent men, and led them into unseemly contradiction to others quite as eminent as themselves. The evil arises from a deficiency in logical habits of thinking, whereby the clearness of abstract truth is obscured by the grossness of mere concrete forms; and separable accidents, merely because they may be very common, are mistaken for essentialities. To illustrate this unfamiliar point in a familiar manner, let me say that men are generally from five feet four to six feet high, and any departure above or below five feet eight inches, the medium, whether rare or common, is an accident. Men of five feet, or six feet and a half, may represent the very common fact accidental, while men of three or eight feet may represent the very uncommon fact accidental, yet both, as facts, are equally certain, and also equally accidental. There is no essentiality of man as connected with height, yet he who mistook the accident for the essential might proceed to deny, that a man could be either found of three feet high, or of nine, whereas both suppositions are not only possible but true. By the mode of argument, however, which I have employed, with regard to the fulness or emptiness of the heart after syncope, you will perceive that you are carried superior to any such limited fields of experience; you become able to reconcile facts apparently at variance, and from your calmer altitude, you are placed above those petty differences and narrow views which must, of necessity, belong to the inhabitants of a lower atmosphere. I consider it not only my privilege, but my duty, thus to enforce those principles upon your minds which have relation to the conduct of the understanding in medical affairs. Matters of fact must necessarily be furnished to you in vast abundance, but they will be little better than a dead manure in your education, unless you be further vivified with a close and discriminating acumen that shall pierce into the penetralia of nature, and be able to select those essential elements of knowledge which constitute the sap of a wise judgment.

This paralysis of the heart being dependent on the diminution, the arrest, or the annihilation of its irritability, only one rule can be applied to its treatment, and that is the employment of stimulants. When the irritability is utterly exhausted, as in the cases of which I have been speaking, of course nothing whatever will prove successful. Yet there are many occasions where such an effect would seem to have been produced, and which doubtless would have continued till recovery was impossible; but in which death has been averted by the timely employment of the means of resuscitation. Thus, in syncope arising from loss of blood, we have already seen that life has been frequently preserved by the simple gravitation of blood towards the head, while the patient was laid with that part of the body very low. Likewise, under hydrocyanic acid, the action of the heart has been re-excited by a sudden dash of cold water, or the actual cautery, or ammonia. It has already been observed that the latter agent is one of peculiar value in all cases of syncope, as from its gaseous form it may be almost instantaneously applied as a potent stimulus to the vast ramifications of those nerves of respiration, which likewise extend to the surface and tissues of the heart; whereas, any attempt to administer solid and fluid medicines during the syncope, would not merely be almost impossible under the circumstances, but highly dangerous, as tending to induce death by suffocation, even after the heart might have rallied from its torpor. The skin and the lungs therefore, must be the media through which we apply our stimulants in a case of syncope, and should the stomach contain any poison which caused the suspended animation, neutralising draughts had better be injected into that organ by means of a pipe, than poured into the mouth.

LECTURE

ON THE

DISEASES OF CHILDREN.

DELIVERED IN THE

Chatham Street School of Medicine, Manchester,

By Dr. MEREI,

Fellow of the Hungarian Academy, late Professor of the History of Medicine at the University of Pesth, Clinical Professor of the Diseases of Children, and Director of the Children's Hospital at Pesth; Fellow of the Imperial Society of Medicine at Vienna, etc.

LECTURE II.

General Remarks on the Physiology and Pathology of Children—Objective Symptoms—The Head—The Throat.

Gentlemen,—When we speak of "diseases of children," we understand all diseases whatever, if developed in an infant or young child; according to the different age or degree of organic development, all diseases are modified in their symptomatic appearance, and in their course and mode of treatment. But then, just as some chronic and organic affections of adults or old people never occur in the early period of life, as for example, hypertrophy or atrophy of the heart, aneurism, certain degenerations of the liver, spleen, or kidneys, tænia, &c., so, on the other hand, there are some diseases proper to infants and children, which hardly ever, or very seldom, are observed in adults. These are "diseases of infancy and childhood."

As the most exclusively infantile may be considered the following:—Trismus, hydrocephalus, rachitis, cancrum oris, and *muguet;* spasmus laryngeus, and eclampsia, which have so much resemblance to some forms of hysteric affections; also croup and hooping cough, which occur sometimes just in the same form in adults, and eruptive fevers, which are very frequently seen much beyond the age of puberty. There are still some other forms or special modifications of maladies, such as chorea, the ophthalmy and jaundice of newly-born children, &c., and besides these, some congenital malformations. These diseases, proper to infancy and childhood, are less frequent, and by no means more important in practice than other maladies—febrile, inflammatory, acute or chronic, common to all ages. If some of the gentlemen present will recollect rheumatic or gastric fevers, with all that variety of complaints, as these affections occur in their practice, with many symptoms only to be learnt from the words and local indications of the patients, and if you imagine then a little speechless child placed under the like circumstances, the difference between both series of patients will be very evident, and apparently more difficulty will be attached to the latter; consequently all diseases to which children are subject, merit to be all the more carefully studied.

Authors have endeavoured to establish certain periods in the progressive life of the child, attached to some salient physiological processes, and consequent dispositions to certain diseases. These attempts are more or less imperfect, as in nature all is but gradual transition. I find it much more important in any treatise on diseases of children, to pay a particular attention to the *two first years of life;* not only because some diseases are nearly exclusively restricted to that tender age, but because all are the most dangerous in their course, the most difficult to distinguish, and the most delicate to manage in this age. There is no speech by which such little patients could enlighten us; and there is the delicacy of their stomach, easily deranged by medicines.

The *physiological character* of infancy and tender childhood I am accustomed to delineate in few words, namely, much delicacy of organic structure, much sensibility and mobility, and want of strength. This qualification is applicable to the nervous, the vascular, and the vegetative sphere of life, and consequently also to the three respective classes of maladies. Supposing that everybody present knows the particulars of the physiology of the early periods of life, I shall merely limit myself to pointing out the great secretory activity of the salivary glands and mucous membranes in this age; then, above all, the regular course of *three* important processes of development, viz., the commencement of dentition between the sixth and the eighth month, the closure of the fontanelles about the twelfth month, finally, that degree of locomotive power in the legs which enables the child to walk about the thirteenth or fourteenth month. If these three scales of progressive development take place sooner, it is of little importance, but if later than at the mentioned terms, it signifies weakness in the constitution of the child, and in particular a scrofulous or rachitic disposition.

According to the adduced general physiological character of delicacy of structure, sensibility, mobility, and weakness, children are more easily and more frequently deranged in their health than adults; their diseases run proportionally more quickly, either to recovery or to death. Slight, even inappreciable causes, are able to put the nervous system into a tremendous disorder, and destroy the child's life. Pure nervous convulsions are very frequent in the tender age. Inflammations run quickly, either to resolution, transudation, or suppuration. With regard to the vegetative system, children are the most liable to alterations of the fluids and of the organic structure. Rachitis affords a striking example. There is an eminent disposition to sympathetic symptoms and affections; gastric derangement, dentition, worms, a paroxysm of intermittent fever, cause sometimes severe fits of convulsion. The high degree of sensibility and mobility is the source of the great frequency of frebrile movements, but at the same time of the unsteadiness or the remittent character of almost all sorts of fevers. The weakness of the organic power at this tender age prevents the development of some severe diseases to that height at which we observe them in adults. An infant seldom arrives at the third stage of extensive lobar pneumonia, or to the acme of typhus. There is a great disposition to

diseases of the mucous membranes and of the skin, both very contagious in children.

Objective symptomatology and physical examination.—In order to facilitate the synthetic proceeding of diagnosis, it is important to study and analyze the single phenomena which from the child fall under the perception of our senses. I shall mention the most conclusive.

The *head.* We observe the proportion between the volume of the skull and that of the face. A large skull, and a small face, is the sign of a scrofulous, rachitic, or eminently nervous complexion. In the latter case the abdomen and legs may be quite regular; in both the former, we find a large abdomen and flabby legs. We likewise observe some salient protuberances, (two, three, four, or five,) two of which laterally on the front, two on the parietal bones, and one at the occiput, impart frequently an angular form to the head; this is frequently the case with the large skull of scrofulous or rachitic children. The retarded ossification of the fontanelles is of the same signification.

The expression of the *face* is a sort of speculum for the practitioner. The bloated face, characteristic in hooping cough, is connected with an abnormal turgor round the eyes; the bloated face in rickets, on the contrary, with a furrow along the lower eyelid, (I would call it circled eyes); the collapsed face, with sunken, excavated eyes, and a high expression of languor—proper to acute diseases; the senile face, meagre, wrinkled, without languor—proper to chronic, scrofulous, and atrophic affections; the superintelligent face, with (proportionally to the age,) too much expression of seriousness and intelligence, frequent in scrofulous and nervous constitutions.

The *eyes* have a great share in the mentioned expressions. The expression of languor arises almost entirely from the eyes. Increased contractility, or *contraction of the pupil*, is proper to the first stage of meningitis, but we observe it also sometimes in pure nervous cerebral irritation, and during convulsions. *Dilated* pupil obtains sometimes in typhus, but much more in cerebral transudation.

I shall pass over the examination of the *ears* and the mouth, including that of the teeth and the tongue; but, with regard to the latter, we find it proportionally to the same diseases more moist than in adults. Suckling children have in general a white mucous coat over their tongue. Before the fourth year it is very seldom we see a dry and brown furred tongue.

The *facial lines.* Certain lines, or slight furrows, very commonly perceptible in meagre faces of adults, are hardly present on the healthy turgid face of a little child; but some of these lines appear eminently under the influence of certain diseases, and impart to the face of the child a more or less characteristic expression. These lines have been studied by Eusébe de Salles and Billard, of Paris, and termed by those physicians *facial lines.* I shall mention the three following:—

1. The *oculo-zygomatic line*, from the interior angle of the eye towards the middle of the zygoma. This I find the most valuable of all; there is only the alternative of an affection of the brain, and of a recent very severe diarrhœa; consequently, if this latter be not present, we may be induced to believe in the probability of an affection of the brain.

2. The *naso-buccal*, from the ala nasi running in a semi-circular form over the anterior part of the cheek, around the angles of the mouth; sometimes accompanied by another short one, which is called the labial. This line is said to signify severe abdominal affections; but the fact is, that we see it very frequently in all sorts of chronic and consumptive diseases.

3. The *mental line* (chin line), commencing near the angles of the mouth and running downwards laterally to the chin, which is regarded too, as a sign of pulmonary affections; but I can state, that this line is only seen in high degrees of dyspnœa, consequently it is also visible in the dyspnœa which depends upon the rachitic compression of the chest, without disease of the lungs.

Some more particulars may be adduced with regard to the signification of the lines and furrows in the child's face. I shall take an opportunity to show from time to time these facial lines and angular skulls, on appropriate individuals, as brought before us.

The *nocturnal head sweats* merit to be mentioned. They consist of abundant perspiration limited to the head, of a disagreable somewhat acid smell, leaving on the linen a dirty stain, of an undetermined colour, and occurring on some children regularly every night. This partial perspiration I observe the most frequently during the second year of age, in children presenting a large skull, retarded osseous and muscular development, suffering or disposed to impetiginous scrofula, hypertrophy of the brain, rachitis, or hydrocephalus. This sweat seems to be a critical effort of nature against the before-mentioned diseases; as I observed in many instances, that, upon its suddenly ceasing, one or the other of those diseases broke out. It is interesting to know that this perspiration subsided in a short time and without any bad consequences, under the influence of *high* doses of *iodide of potassium*, carried to the degree of iodine fever. This I have experienced in many cases, and at the same time I observed an improvement, that is to say, a lessening of the scrofulo-impetiginous habit.

The *throat*, outside and inside, the latter as far as accessible, frequently affords some phenomena, the signification of which can hardly be mistaken. The difficulty consists rather in the resisting efforts of the child, which we encounter frequently as soon as we intend to depress the tongue, in order to look at the pharyngeal or laryngeal parts. By the assistance, however, of one or two clever persons, we get rid, if necessary, of these difficulties. (Some details on the mode of examining the inside of the mouth and the throat.)

On the next occasion we shall speak of the symptoms and physical examination of the organs of the chest, a subject interesting as well as important, by its perfection attained in modern times.

CASES IN MIDWIFERY.

By THOMAS RADFORD, M.D., F.R.C.P., Edin., &c., &c., &c.

Consulting Physician to the Manchester and Salford Lying-in Hospital.

Case II.

Cæsarean Section.—*(Successful.)*

Before entering on the relation of the following case of successful Cæsarean section, it is proper to state that it has been already twice brought before the profession by Mr. Goodman, with whom I was engaged in it. It was first partially cited in the *London Medical Gazette*, vol. 36, page 1506. I took great interest in its result, and kept a daily and very circumstantial account, with the intention (having previously obtained Mr. Goodman's full and kind permission) of publishing it with some remarks. In his statement (*loc. cit.*) he says, "Considering this case to be one of deep interest to the profession, I have forwarded it to you in its present stage; but when the patient is completely recovered, which there is every reason to expect, Dr. Radford, who has been for many years specially devoted to this branch of the profession, will on some future occasion furnish the profession with the more minute details, and at the same time give his own views upon the subject." Afterwards it was inserted in the first volume of the *British Record*, with an account of her subsequent pregnancy and abortion. Some discrepancies will be found in the dates mentioned in my statement and those stated in the *Record*; but I have no doubt it has arisen solely from mistake. However tedious a detailed account may prove to the reader, I considered its importance fully justifies me in giving a full exposition.

Case.—At half-past one o'clock A.M., Thursday, Nov. 20th, 1845, I visited Mrs. Sankey, Bedford Street, Salford, who was then in labour. I met Mr. John Goodman, from whom I learnt that the case was one of extreme distortion of the pelvis, &c. She first felt slight pains about eleven o'clock on Wednesday morning. Sometimes they were stronger, and continued to vary in severity until about three hours before my arrival, during which time they were uniformly stronger. The membranes ruptured some time in the afternoon, and there was a slight dribbling discharge at intervals up to the time of my first visit. The tongue was clean and moist; her countenance was calm and composed; her bowels had been freely evacuated; and she had regularly passed her urine. She was free from sickness and vomiting. Pulse 84 at first, but temporarily rose to 100.

Placing my hand on the abdomen I found the uterus of a spheroidal shape, but less so than I had observed in former cases; it felt firm and free from pain when I pressed upon it. The relative position of this organ was now much altered; it hung over, and rested on the pubes, and the fundus projected so much forwards as actually to form its anterior surface. Connected with, and in reference to the axis of the vagina, it presented the retort form. By a vaginal examination, I found the outlet of the pelvis considerably diminished by the close approximation of the rami of the ischia and pubes, which, jutting forwards, had nearly destroyed the arch, leaving in its place only a narrow slit, which would barely admit the point of the finger. The tubera of the ischia were so near as scarcely allowed two fingers to lie in the transverse diameter; the antero-posterior diameter was also much shortened by the great incurvation of the coccyx and lower portion of the sacrum. The cavity was diminished by the several bones which unite in each acetabulum being forced inwards, backwards, and upwards. It was difficult to measure the brim; its figure was tripartite. This alteration in shape was produced by the falling down of the promontory of the sacrum and lumbar vetebræ, and by the ischia and pubes being pushed backwards and inwards, and the jutting forwards of the symphysis and rami of the pubes. The antero-posterior diameter was not more than an inch and a half at its widest part on the right side, and in some parts not an inch. The anterior lobe of the opening was not more than would admit the finger edgeways. The vagina was moist, and had only its natural temperature; it was free from swelling. Neither the os uteri nor the presentation of the infant could be felt.

On returning down stairs to Mr. Goodman, I cordially agreed with him that the Cæsarean section was the only means by which delivery could be performed. I suggested the propriety of having the stethoscope applied to notify whether the infant was alive as the mother affirmed, and also to ascertain the location of the placenta. At this stage I also requested that Mr. Winterbottom, surgeon, should be invited; a messenger (Mr. S.) was dispatched for Mr. Winterbottom, who was desired to bring with him a stethoscope. I now remarked on the danger of cutting into and partially separating the placenta during the operation. Auscultation indicated that this organ was attached to the anterior and right lateral portion of the uterus, and corroborated statements made by the patient that the infant was alive. I now raised the fundus uteri, and Mr. Goodman made an incision from seven to eight inches long, a little to the left of the umbilicus, and divided the integuments, which were extremely thin. A corresponding opening was then made through the uterine tissue, which was about a quarter or one-third of an inch in thickness, just bordering on the edge of the placenta. I now passed my hand and seized one leg of the infant and extracted it, and when it passed to the head, Mr. Goodman assisted its escape through the wound, and afterwards expeditiously extracted the placenta entire. The infant, a girl, was alive. There was very little blood indeed lost, and the uterus contracted and lowered itself to its resting place. The intestines and omentum protruded during the operation, but were then restrained and afterwards replaced and retained in their natural position during the time the ligatures were introduced. I swept my finger round the boundary of the uterus and through the wound into its

cavity, to ascertain if any portion of the viscera had got into it. The *interrupted suture* was used, and the thin integuments further brought together by straps of adhesive plaster, and over all a bandage just tight enough to give support was applied. There was a calmness and resignation of mind throughout the entire operation which indicated an enduring Christian spirit; no complaint was made, nor murmur heard, and she expressed herself as happily relieved.

The pulse now beat 92. She had a little gulping; the skin felt warm. To have Tinct. Opii, dr. iss. in about one to two hours; pulse 94; slight retching, and a very trifling oozing of blood was seen on the bandage; her lips were naturally red; respiration 26; fresh bandage and a compress applied.

Quarter-past nine o'clock A.M. Tongue clean; countenance natural; respiration 24; about two to three ounces of blood lost. A negative plan recommended. Mist. Acaciæ, oz. j. vel. oz. iss. ter in die.

Eight o'clock *vespere.*—Pulse reduced from 100 to 90; countenance good; had complained of tightness of the bandage; the belly a little tumefied, but not tender; there is no bleeding. To take Ext. Hyoscyam., gr. x.

November 21st.—Ten o'clock A.M.—Had vomited a sour fluid during the night. Pulse 86. Countenance natural; tongue clean and smooth; skin cool; lochial discharge natural; bowels not moved. Had passed her urine. Ordered an enema as follows:—Spt. Terebinth., oz. ij.; Ol. Ricini, oz. j.; Vitelli. Ov. et Dec. Hord. q. s.

Half-past one o'clock P.M.—Tongue clean; she has vomited a dark-coloured thick and sour fluid, which in appearance looks like fæces. Enema has not operated; ordered it to be repeated, and to take barley-water.

Nine o'clock, *vespere.*—Has had no stool; vomiting continues; belly tympanitic. The compress being removed, the site of the lower portion of the abdominal wound was tumid; and on raising the plaster, the wound itself was seen gaping, and a fold or convolution of intestine had protruded through between (in the interstice of) the two ligatures. The bandage and plasters were now entirely removed. An attempt was made to reduce the bowel, and the edges of the wound well adapted, and fresh straps of plaster and a three-tailed bandage applied. Ordered, at her request, Ol. Ricini, oz. ss.; to be repeated if necessary.

22nd.—Nine o'clock A.M.—Had some sleep. Pulse 100. Had vomited the oil, and also some of the same fluid. Tongue clean; bowels less swelled, but slightly sore; there is a considerable bloody serous discharge from the wound; has passed urine; lochial discharge; has had no stool. To take calomel, gr. v.; a quantity of gruel to be thrown up by the syringe, with the œsophagus tube passed high up towards the sigmoid flexure of the colon.

Seven o'clock *vespere.*—Has slept several times; pulse 90 to 95; feels better; skin cool; vomiting ceased; belly less swelled and easy; and another enema had been administered, but it procured no stool. Ordered—Calomel, gr. v.; Sacchar. Alb, gr. v., s. s. R. Magnes. Sulph. dr. vj.; Magnes. Calcinat., dr. ij.; Tinct. Card. Comp. dr. j.; Aq. Cinnam., oz. iij.; cap. coch. larg. j. tertiis horis.

23rd.—Ten o'clock A.M.—She had slept; pulse 90; tongue clean; had vomited only once a light-coloured fluid; bowels opened four times; skin warm and perspiring; very slight abdominal uneasiness.

Five o'clock *vespere.*—Had visited her before and found her going on well; a considerable serous discharge from the wound; had not vomited; has had three stools; has passed urine; has had several sleeps. To continue Mist. Acac.

24th.—Ten o'clock A.M.—Pulse 95; tongue clean, but redder in the centre; has very little abdominal pain on pressure; bowels purged two or three times; has passed urine; she says she feels weak. Pergat. To take beef-tea.

Half-past seven o'clock *vespere.*—Pulse 100; tongue clean but sore; belly less tumefied, and bears pressure; a considerable bloody serous discharge from the wound; had been twice purged, and attended with griping pain. To continue the medicine and to take half an ounce of the following mixture if the diarrhœa continues:—Cretæ, dr. j.; Mist Acac., oz. iss.; Aq. Dist., oz. j.; Tinct. Opii, dr. j.—R. Opii, gr. ss.; Conf. Aromat., q. s. Fiat pil. horâ somni sumend.

25th.—Ten o'clock A.M.—Pulse 94; tongue clean; had slept; lochial discharge natural; had passed urine; bowels not again moved; gentle perspirations; belly easy. Pergat. Ordered chicken broth.

Half-past four o'clock P.M.—Pulse 85; symptoms all favourable; has a cough. Taken freely of chicken broth and beef-tea. Ext. Hyos., gr. x., horâ somni. Mist. Acac., oz. ij.; Tinct. Camph. Co., dr. iij.; Syr. Rhœad, oz. ss.; Ft. Linct. cujus. capt. coch., min. j. urgenti tusse.

26th.—Ten o'clock A.M.—Pulse 94; tongue clean; skin a little hotter; bowels unmoved and tympanitic; had passed urine; her countenance a little more anxious. The bandage and plasters were removed. The ligatures were detached from their hold; the integuments expanded to such a degree as to present a large surface of the bowels, which were uniformly covered with lymph. The incised edges were firmly agglutinated to the contiguous parts. Attempts were made to bring the integumental edges nearer together, and the bowels were gently pushed back, and broad straps of adhesive plaster were tightly applied, and a six-tailed bandage, so as to afford firm and equal support. Ordered—Mist. c. Magnes. Sulph., dr. vj.; Magnes. Calcin., dr. ij.; Aq. oz., vj. cujus. capt. oz. j., tertiis horis donec alv. resp.; and the following form for an enema, to be administered if necessary:—R. Spt. Terebinth., oz. ij.; Tinct. Assaf., dr. ij.; Aq., oz. vss.; to be added to eight ounces of barley-water.

Six o'clock *vespere.*—Pulse 120; skin hotter; has great depression; tongue dry; countenance anxious; bowels unmoved, complains of pain in the belly; has passed water. Ordered the enema to be immediately thrown up. She has just vomited. Pergat. An anodyne to be prescribed.

27th.—Took Morph. Acet., gr. $^1/_6$; c. Extr. Pot. gr. iij. She has had four motions; has slept well; and generally better. Pulse 60 to 26. Cont. Mist. Acac. Linctus. Beef-tea; and to take anodyne at bed-time.

28th.—Pulse 69; has slept well; has had two motions; a considerable discharge from the wound; all the other symptoms better except the cough, which is rather more troublesome. Continue medicine and diet; and isinglass.

29th.—Pulse 84 to 90; slept well; bowels twice naturally moved, all the symptoms more favourable; a considerable discharge on the bandage. Upon removing the bandage and dressings the wound presented a healthy granulating surface, and was covered with pure pus. There was a small slough at the lower edge. The integuments below in the bend of the thigh, were irritated and excoriated by the discharge. Continue diet and medicine.

30th.—Pulse 86 to 100; tongue clean and smooth; bowels moved: complains of sore throat, which is red and slightly apthous. Cough very troublesome, and, from its force, produces a sensation of forcing some part through the wound, and on examination a portion of bowel was found protruded. The lower part of the bandage and dressing being now removed it was seen to be not so well; the granulations were paler; the discharge from the left was blackish, from the slough. Fresh pledget of lint and plaster applied. Continue the same medicine and diet, and also to have eggs, and the following mixture:—R. Sodæ Sub-borat. Pulv. dr. iij.; Syrup. Rhœad., oz. ss.; Mist Acaciæ, oz. iiss, M. Capt. paululum subinde. —R. Morph. Acet., gr. $^1/_4$; Extr. Papav., Al., gr. iij. Ft. pil. horâ somni sumend. et rept. si op. sit.

December 1st.—Pulse 100; all other general symptoms better. A considerable discharge from the sore, which was dark coloured and offensive; a protrusion of the granulated portion of the sore through the dressings, which were now removed. The aspect of the sore pale, its left edge was sloughy in places. The dressings were changed, for pledgets of lint with cerate, over which double folds of lint were placed, and a six-tailed bandage to support as far as possible. Our object was to form a barrier to further protrusion, as from the intimate adhesions which now existed amongst the convolutions of the bowels themselves, and between them and the integument, it would be mischievous to attempt to do more than to defend and barely support these parts. On the right side the old and new surface presented one plane. To take a generous diet and porter, and also the anodyne pill.

December 2nd.—All the general symptoms favourable; had first refused to take porter but afterwards did so; wound looks better; granulations redder; pus laudable; cicatrization on the left side proceeding; sloughy appearance on the right side much better. Continue diet, porter, and night pill. At the evening visit she reported she had taken beefsteak and porter at dinner, and we found her eating the leg of a fowl, and again drinking porter. Cautions given not to get into excess.

3rd.—Mr. Goodman, at a later visit last night, found her pulse considerably more frequent. She complained of the wound. On examination he discovered that a large loop of intestine had protruded on the left side, which he unsuccessfully attempted to reduce. He placed a pledget of lint with cerate over it. This morning the pulse 120; bowels not moved; she had vomited some undigested animal food. The body linen was very wet by discharge, which had a pungent disagreeable smell. The dressings adhered so firmly that they were with difficulty removed. A loop of intestine of a horseshoe shape, covered with lymph, was fixed by adhesion; it was very much distended. Cautious but unsuccessful attempts were made to reduce it. I suggested the propriety to pierce it with a needle; a sharp-pointed bistoury was, however, used, but nothing but a little blood escaped. Another unsuccessful attempt was made to reduce it. Broad slips of plaster and a bandage applied. An enema, with oil, &c., to be thrown up with the syringe and œsophagus tube. To discontinue the porter and animal food; to take chicken broth. Ordered some coriander or mustard seed to be taken, and the anodyne pills.

4th.—Bowels freely moved several times, but the seeds were not seen. All the symptoms better. Continue.

5th.—Bowels three times moved, and in the last motion the coriander seeds were seen: every other general symptom favourable. The wound healthy. The union on the right side complete, and the cicatrization proceeding. On the left side the loop still lay prominent, and the edges of the sore were everted, and in an unfavourable position for this reparative process. Continue diet and anodyne pills.

6th.—Pulse 95; bowels unmoved; slept well; wound looking healthy, lessening in diameter, cicatrization rapidly proceeding; the surface over the protruded intestinal loop granulating; this portion of bowel immoveably fixed down. Continue medicine, to have an enema and her anodyne pill.

7th.—Pulse 90; bowels twice very freely moved, and in one motion some coriander seeds were found; a profuse irritating discharge through the dressing; on exposing the parts an opening was found at the lower end of the protruded bowel, through which fæces had passed, and were now escaping; the enema had not been given, but it was now directed to be administered. To continue to take the anodyne.

8th.—Pulse 90; slept well; bowels once opened by the enema; the size of the wound is considerably diminished, and its surface looks healthy; fæces in great abundance were discharged through the intestinal opening; to continue the same plan. Ordered an enema and anodyne pills.

9th.—Pulse 84; bowels opened by enema; the wound is diminished in size and looks healthy; the fæces are largely discharged through the opening in the bowel To try to eat some calves' foot. To continue to have an enema and the anodyne.

10th.—Pulse 80 to 84; the wound considerably lessened, and its entire surface looks well; the apparent size of the protruded bowel is greatly diminished, and

it is covered with healthy granulations; its horseshoe character is nearly lost; great quantity of feculent matter comes through the opening; portion of undigested calves' foot was observed in the discharge; ordered a little wine. Continue diet. To have an enema and pill.

11th.—Pulse 74; wound lessened and looks well; bowels moved by enema; fæces in great abundance from the opening. To continue wine, &c.

12th.—Pulse 72; had two stools, which were too light in colour; this perhaps depends on the escape of the biliary fluid too soon, as the fæcal discharge by the opening has been all along very deeply tinged, and is still in great quantity; the sore is now considerably lessened, it does not measure more than four inches in length, and two to two and half in breadth; the protruded intestine so far retired as not to be seen, except when the integument is drawn aside; the integumental edges of the sore can now be approximated. To continue the wine, &c.; to have an enema; and to take the pill.

13th.—Pulse 74; right edge of the wound was more inverted, which had been produced by approximating the two sides; bowels slightly moved; considerable fæcal discharge from the wound, and in it some coriander seeds were seen which had been taken early in the day; the wound dressed in its longitudinal direction. Continue the wine, &c.; to have an enema; to take the pills.

14th.—Pulse 72; has had no motion; granulations paler; the discharge of fæcal matter great through the wound; a sponge compress was applied over the opening, which was to be removed at intervals; it was, however, permanently discontinued in the evening. Continue wine; to have jelly, *blancmange*, isinglass, and to be allowed a partridge.

15th.—Pulse 76; small hard fragment of stool brought away with the enema; countenance more dejected; complains this morning of a load at the stomach, which in the course of the day ended in vomiting of a quantity of undigested animal food; the fæcal discharge great from the wound. As the granulations were exuberant, the sore was dressed with dry lint. Wine increased; continue altera.

16th.—Pulse 74; wound less and looks better; bowels not moved. To only have some broth, with a little of the chicken pounded in it. Continue medicine. To have an enema.

20th.—No particular change in the aspect of the case up to this date. Pulse now 74. The fæces still largely discharged from the intestinal opening. The protruded portion of bowel very red from the everted mucous membrane. Mr. G. passed his little finger and carried this part in. A compress was applied and supported by plaster.

31st.—During this interval the pulse nearly uniformly 72. Bowels some days spontaneously moved once or twice; but nevertheless an enema was daily administered. All the general symptoms continue to improve; and the excoriations produced by the discharge were attended to by washing, &c. The everted mucous membrane of the bowel which appeared through the opening had at first rather increased, but now was considerably less. Compresses or pads were applied, &c. The discharge of fæcal matter through the opening has gradually lessened.

January 10th, 1846.—As in the last report, the pulse had uniformly continued steady. The bowels were sometimes moved more than once a day; the enemas were regularly administered; the everted state of the mucous membrane of the bowel varied in degree and in colour. Her spirits were very low on the 4th, in consequence of the very great discharge which took place through the opening in the bowel. The treatment consisted of small pads placed immediately over the aperture, being supported by small slips of adhesive plaster; and then upon the integuments and over the other a larger pad, &c., fixed by broad straps and bandage.

17th.—Since the last report the pulse continued natural, and she slept well, and her appetite was good. The bowels were naturally opened once or twice a day; and therefore the enema had been discontinued until the 14th ult., when the bowels being only partially moved, and as the belly had become more tumid, they were again used; the discharge from the intestinal opening was at first less solid and more serous, but afterwards it became again more feculent; compresses of different kinds were applied, and one suggested by me, made of layers of caoutchouc was used, but did not succeed; on this day the fæcal discharge was much greater, which I accounted for by the opening, which was about the size of a fourpenny piece, having changed its relative position with the integuments. I recommended that a conical piece of sponge should be placed with its point inwards, and be supported by plaster and bandage. Mr. Goodman feared that it would be injurious to use the sponge, as it might dilate the opening and induce ulceration; my reply was that I did not fear the first effect, and if the second happened it would only be limited in degree, and advantageous. I thought at this time the edges of the wound were in a favourable position to be pared, and a ligature used to bring them into apposition.

22nd.—Pulse kept natural, and the bowels were daily moved twice; the sponge had become a little swelled, and the edges of the opening bled a little; it was reapplied on the 20th; the bandage was very wet, and was attended by a disagreeable ammoniacal smell, which no doubt arose from the decomposition of the discharged fluid which had taken place in consequence of the parts not having been dressed the day before, and the surrounding integuments were considerably irritated and excoriated; at my desire a simple dressing with lint and cerate was adopted, and a very loose bandage applied. The patient had sat up, but the horizontal position was advised. On this day (22nd.) the eversion of the mucous membrane was greater, and the opening had slightly increased; a piece of sponge was recommended by me, but a compress of lint was applied at Mr. Goodman's desire.

January 23rd.—Pulse good; bowels twice moved; the integumental excoriation rather extended; the intestinal opening is a little larger. Mr. Goodman

proposed touching its edges with Argent. Nitr., but I considered that the surface would heal underneath before the eschar separated and suggested the Potassa Fusa. Mr. G. thought it would be difficult to limit its application although, my opinion was that its action might be controlled, I recommended instead of it the edges of the opening to be pared off, which Mr. G. did by a lancet and bistoury. This operation was not so effectually done in consequence of the tender and fragile state of the part. The edges ware approximated and supported by slips of adhesive plaster. The integuments being drawn together formed a covering and compress to the aperture.

31st.—During this interval the pulse was natural, and the bowels some days moved spontaneously, and always responded to the use of an enema. The intestinal opening remained much the same, and the discharge from it, although not equal in amount every day, was yet sometimes very great. Various methods were tried to control it. Pitch plasters in different ways, and compresses, were used, at the suggestion of Mr. Goodman, but they invariably failed to do good, on the contrary mischief was done by them. At my request pads made from caoutchouc, of different sizes, and placed differently, were employed, but equally unsuccessfully. I recommended broad straps of plaster from the Infirmary to be tried, which also failed, as considerable irritation and excoriation had been produced by the pitch plaster; indeed the pain and inconvenience sustained by the patient was such, that she not only requested a discontinuance, but strongly protested against its use. My opinion was unfavourable to their use, as I considered disadvantages from them arose, not only on account of the irritation, &c., arising from the pitch itself, but from the mechanical effects by inflecting the integuments upon each other, and also by impeding, by the great pressure produced, the peristaltic motion of the bowels. On the 30th I saw the patient alone, and thought it would be better to apply a simple dressing.

February 1st to 13th.—It appears that a great discharge issued from the opening after the last dressing, so that the nurse, at the desire of Mrs. Sankey, had removed them, and brought the edges together by adhesive plaster. Long straps of plaster were again recommended by Mr. Goodman, and very tightly applied, some of which were passed round from one side of the spine to the other. Great integumental irritation and excoriation ensued, and it was, therefore, thought desirable not to bind the parts so tightly. The edges of the opening were touched from time to time with the Argent. Nitrat.

2nd.—I suggested the propriety of having a bandage made of some elastic but firm material, so that the diaphragm and abdominal muscles could move in opposite direction, and without the least impediment, and at the same time feel uniform support.

11th.—Mrs. Sankey stated that they had removed the quill, as nothing had passed through it. Mr. Goodman had placed the barrel of a quill as a conductor for the fæcal discharge, but this it appears did not answer, nor was it likely to do so, as it would be quite impossible to place such a body in a parallel direction with the course of the intestinal tube; and we cannot for a moment suppose that it could act by suction.

12th.—I found that pitch had been used again in dressing the part the day before; the evils were increased by this plan, the surrounding irritation and excoriation were seen to be much greater. Mr. Goodman ordered a new bandage, with gussets for the hips, and buckles and straps were attached to it, so that it could be tightened and fixed. This contrivance proved of great advantage to her. She wore it for a considerable time, and Mr. Goodman states he had the satisfaction to find a progressive diminution of the fæcal discharge which passed through the intestinal aperture.

Remarks.—Mrs. Sankey's occupation was merely domestic. She was a slender, delicate, and spare-looking woman. Her complexion was pale, her skin was swarthy, her eyes were grey, and she was of a leuco-phlegmatic constitution. She was naturally of a mild and placid disposition, and her mind was placable, and strongly imbued with sound moral and religious principles, which wonderfully supported her in her severe trial, the intensity of which it is scarcely possible for imagination to conceive. What can be more dreadful than the anxieties of a woman in the pangs of labour without hope of delivery? She bore the operation with great fortitude, and scarcely made a moan, and afterwards endured a tedious recovery with great patience and resignation. Her age was 41 years. This was her seventh pregnancy. Her first four labours were natural and easy. In the first she was delivered of a living girl, and in the other three of boys, all born alive. The fifth labour was natural, but it was rather more tedious than her former ones; the infant (a boy) was born alive. At the end of two years she was again in labour of her sixth child, which was protracted by pelvic distortion, and Mr. Goodman, with Mr. Slack's assistance, delivered her by means of the perforator and crotchet.

The disease (mollities ossium) under which she now suffered no doubt commenced after her fifth labour, which proved a little tedious. It is, however, very probable, that the mischief inflicted on the pelvis was only slight at this period, and during the interval between it and her next pregnancy most likely the disease remained stationary; whilst pregnant of her sixth child it rapidly advanced, and committed great ravages in the pelvis. Her general health suffered, and her strength failed. Her stature became obviously less. Mr. Goodman kindly informed me that the thighs somewhat bowed, but afterwards recovered the usual shape. During her labour Mr. Goodman found the pelvic diameters shortened, the antero-posterior only measured about two inches. After a consultation with Mr. Slack, he delivered her with the perforator and crotchet. It, however, rarely happens, that the disease is so rapid in its progress, and does so much injury to the pelvis as to require these murderous instruments before those which are compatible with the safety of the

infant, have been used in a former labour. After her puerperal recovery Mr. Goodman judiciously prescribed for her tonics and other appropriate remedies, and recommended her to the seaside for the benefit of bathing. Her health was greatly improved, and perhaps the progress of the mollities osseum was temporarily arrested. This disease again returned, and produced effects on the pelvis during her pregnancy which rendered necessary the Cæsarean section for her delivery. Many circumstances existed in this case which favoured its propitious termination. Her calm and tranquil state of mind, and the high degree of moral courage she had, were very advantageous.

An early rupture of the membranes in protracted labours, especially if the pains are strong is always to be deplored, but most fortunately this did not happen here very long before the performance of the operation. The water was not suddenly and completely discharged at once but dribbled away. The pains were also very feeble until a very short time before my visits. The conjoined effects of these were doubtless favourable, and prevented an injurious pressure on the soft parts. The bowels were freely evacuated during her labour.

By the aid of the stethoscope the incision was made in a direction to avoid cutting into the placenta, which is very important. When the placenta is cut upon or into, partial irregular contraction of the uterus happens, and through such an accident the infants may be lost as I have already stated, but besides this, the tissue of the uterus is likely to suffer from the force required to extricate it (the infant) from the spasmodic grasp of this organ. Besides, there may be a greater risk of hæmorrhage when the placenta is prematurely disruptured or separated. The operation was timely performed in this case. There happened several important contingent circumstances which I shall briefly advert to. The abdominal parietes were so much attenuated as only to allow a very slender hold to be taken by sutures, and were quite unequal to resist the pressure they were subjected to. By the force of the cough, &c., this weak structure was torn through, and the edges being thereby set at liberty, retracted on each side to a considerable extent, and exposed the bowels fully seven to eight inches in one direction, by three to five in the other. Notwithstanding this serious accident the constitutional disturbance was only trifling in degree and of short duration.

The changes which successively took place on the exposed surface of the bowels were truly astonishing. A thin transparent effusion of lymph was first seen laid over the peritoneal coat of the intestines, which entered a little into the depressions formed between their convolutions. This thin gelatinous material gradually became thicker and more opaque, evidently the second step towards cicatrization. During this wonderful process—for its effects were truly wonderful—innumerable vessels were seen, destined to carry on this great work of reparation. As this went on there was a progressive and perceptible diminution in the size of the surface; and when completed there was a cicatrix to be seen very little different from one which is formed at the healing of a wound whose edges have been kept in juxtaposition.

Symptoms of strangulation appeared, for the relief of which several expedients were adopted. The protruded portion of the bowel was ineffectually punctured. Nature, however, stepped in, and immediately the symptoms were relieved by the formation of an opening, through which a great quantity of feculent matter and flatus were discharged. This aperture, as is mentioned in the reports, continued throughout the case. Although this disaster protracted the patient's recovery, there is no doubt it had at the time it happened a most salutary effect. During the whole period of the case the bowels were strictly attended to; and there is no doubt their ready obedience to our measures (chiefly enemata) considerably contributed to her recovery.

The reparative process which happened in this case, and the decidedly conservative constitutional power which this woman had, proved beyond dispute that the opinion expressed by my friend, Dr. West, (*London Medical Gazette*, No. 1210, February, 1851, page 245,) is not infallibly true; and, therefore, ought not to influence us, and deter us from the performance of the Cæsarean section. The same restorative power was observed in the other successful case, which is already before the profession.

As it was important to preserve the infant, I strenuously urged Mr. Sankey to obtain a wet nurse; and no time was lost in obtaining one. The infant continued to thrive, and lived rather more than seven months. Her death was occasioned by an hydrocephaloid disease, the consequence of exhaustion from diarrhœa. In a late number of this journal I mentioned that Mrs. Sankey again became pregnant, aborted, and afterwards died. At the present time I make no further comment.

ON ACETATE OF LEAD.

By WILLIAM SWEETING, Esq., Abbotsbury.

Read at the Dorchester Branch Meeting, May 20, 1851.

At the late Assize for this county a man was tried on a charge of attempting to poison another with acetate of lead. A medical witness deposed before the committing magistrates "that a bottle containing about fifteen ounces of fluid had been conveyed to him for examination. The taste satisfied him that it was a solution of acetate of lead, of which one-third part yielded by analysis nine grains of metallic lead. Hence he was of opinion that the bottle contained three drachms of the acetate;* that this substance is an acrid poison; and although persons had recovered who had taken one drachm, he should be sorry to administer a fifteenth part of that quantity." Upon this opinion the accused was committed to prison,

* A drachm of the acetate yields twenty-seven grains of metallic lead.

where he remained from September to the next gaol delivery, in March.

At the trial the witness before referred to persisted in stating that acetate of lead is decidedly a poison, regardless of the cases reported in the works of Christison and Taylor, to which the counsel for the prisoner directed his attention. Upon this I will merely remark, in the language of Professor Taylor in a somewhat similar case, "that it is impossible to reconcile the facts known concerning the effects of acetate of lead with the strong medical statement here made.*

That vulgar prejudice condemns the acetate of lead as an acrid poison is notorious. It is, therefore, very important, not merely as a question of jurisprudence, but of medical practice, that this substance should be divested of its terrors, and its comparative harmlessness, or rather its value as a medicament, established. With these views I submit to the Association the result of my own observations, in the hope of obtaining the experience of the profession on the subject.

The question to be first solved is—Is acetate of lead a poison?

If we accept as correct the definition of "poison" given by Dr. Johnson—"*That which destroys life by a small quantity, and by means not obvious to the senses,*" it must be admitted that this substance cannot be considered a poison, because, amongst other reasons that may be adduced, there is, I believe, no well authenticated case on record wherein death has followed the administration of it; for surely, that cannot be held to be a poison which has rarely been known to destroy life, although taken in considerable quantities.

Professor Taylor combats Dr. Johnson's definition, which, "if admitted," he remarks, "would exclude a very large class of substances, the poisonous qualities of which cannot be disputed." "Nitre," he goes on to say, "it is well known exerts a poisonous action only in large doses;" and subsequently, in treating of this substance, remarks, that "it is never likely to be employed by a murderer, since a sufficient dose to kill could not be *secretly* administered," herein giving force to a definition he had before denounced.

Several interesting cases wherein acetate of lead has been administered in large quantities without destroying life, are recorded by Dr. Christison and Professor Taylor.

A woman was admitted into Guy's Hospital, in May, 1846, having swallowed *an ounce and a half* of sugar of lead dissolved in water, from which she recovered, and left the hospital in five days.†

Mr. Gorringe reported two cases in which two girls swallowed by mistake *one ounce* of the acetate, and another in which a girl swallowed one drachm, and all recovered.‡

Dr. Hirding gives a case in which a girl swallowed *three drachms*; she, too, recovered.§

Dr. Iliff records *four* cases in which individuals swallowed each *an ounce*;‖ and Dr. Evans one, in which *three drachms* were swallowed, and all in a very short time recovered.* These cases, with the "observations and experiments of Orfila, prove that the vulgar belief that sugar of lead is an active poison, is erroneous."

The more important point to be submitted to the Association refers to the value of acetate of lead as a remedial agent, and in treating on this subject, the result of fourteen years' experience, and the conclusions I have arrived at, are laid before you. I have found that in this substance we possess a most powerful sedative; that it is unequalled in its capability of restraining internal hæmorrhages and intestinal disturbance, and that it may be administered safely in much larger doses than were formerly supposed to be judicious. In the early years of my practice, when cases occurred in which it was deemed desirable to administer the acetate, the dose rarely exceeded one grain, repeated at long intervals, guarded, too, with opium and other adjuncts, in order to avert the injurious effects of what was popularly considered a poison, or at least the probable occasion of colic, palsy, &c.

It happened, about fourteen years since, that I was attending a gentleman's child, about seven years of age, labouring under typhus. I was summoned to him in the night, and found the child apparently sinking from colliquative bloody diarrhœa. There was no time for parleying; unless some very decided measures were adopted he would surely sink. In this emergency I administered *five grains* of the acetate dissolved in distilled water. The effect was immediate and surprising; the diarrhœa was checked, the child rallied, and at length fully recovered.

Soon after the foregoing case two of Asiatic cholera came under my notice. To the first I gave five grains, which were speedily rejected; I then gave one grain every ten minutes. In the course of two hours the diarrhœa, vomiting, and cramps abated, and both patients recovered.

In uterine hæmorrhage I have administered this medicine very largely; the following goes to prove that we have no great reason to fear mischief, either from the quantity or its accumulation:—

A woman of delicate health miscarried, and was nearly exhausted by hæmorrhage, which all the ordinary appliances failed to check. On my visiting the woman I found her pale, bloodless, the extremeties cold, and apparently sinking. Having ascertained that the hæmorrhage was not kept up by coagula retained in the uterus, and that the ovum had been wholly expelled, I gave her *five grains* in distilled water, and repeated it *every hour*. This was persevered in for forty-eight hours. The hæmorrhage was moderated, but as soon as the medicine was suspended, it returned again. I then ordered it to be taken every four hours, and continued it for a fortnight, with the happiest results, and the woman was so conscious of the benefit derived from it that she always kept a supply by her, to be taken as occasion may require. In this case the patient took, in sixteen consecutive days, 576 grains of the acetate.

* The edition of Christison's work now before me was published in 1836; that of Taylor in 1848.

† Taylor, p. 431. ‡ *Ibid.*, p. 432. § *Ibid.*, p. 432. ‖ *Ibid.*, p. 434.

* Taylor, p. 435.

Large as the quantity before stated is, the practice is not without precedent, for Van Swieten administered *sixty grains daily for ten days*,* but what the dose, and at what intervals repeated, does not appear. The largest single dose I ever administered is *twenty grains*. Mr. Daniel, in a paper on its effects as a remedy for mercurial salivation,† states that he has "given *ten grains three times a day*, and never observed it to produce any other unpleasant symptom except a slight colic after the fourth dose."

The boldness with which I have administered the acetate, is not the result of mere speculation, nor of observations made in one month or one year, but rather of patient and careful watching for the long period of *fourteen years*, during which time I have repeatedly directed the attention of my professional friends to the subject, at meetings of the Provincial Association and communications with the periodicals of the day; and I aver, that during all that time I have never met with an instance in which the ill effects usually ascribed to lead have followed the administration of it.

In Professor Taylor's work is a record of a fatal case, extracted from the *Pharmaceutical Journal*, in which a child took in small divided doses, continuously given in the space of *nine weeks*, *thirty-three grains*. It may not be altogether lost time to inquire whether minute doses may not have a tendency to accumulate in the system and produce its specific effects, whilst larger ones are carried out of it readily. A scruple of calomel passes harmlessly through the system; the same quantity given in small doses at certain intervals, produces violent ptyalism. There may be no analogy between these cases; the suggestion is merely thrown out for the purpose of directing future inquiry. I more than half suspect that where acetate of lead, internally administered, has occasioned dangerous symptoms, the preparation has not been free from oxidation—it is the *oxide* which is injurious, it was that which was mixed with the cider in Devonshire, and gave a cognomen to the colic prevalent in that county. The same obtains in *painter's* colic; these people mix considerable quantities of litharge and red lead, technically called driers, with their oils, and neglecting careful ablution before taking their meals, imperceptibly swallow a material of a very dangerous character.

It might be useful to obtain the opinions of the profession with regard to the subject of this paper, by submitting some such questions as the following:—

Have you had much experience in the internal administration of acetate af lead?

In what cases have you administered it?

In what doses and at what intervals?

What effects have been produced?

Have you ever met with an unequivocal case of poisoning by it?

It has been suggested that an objection to the internal administration of acetate of lead is its liability to decomposition by other drugs. There is much justice in the remark, reminding me that I ought to have insisted as essential, that the medicine should always be given, *simply dissolved in distilled water, without any combination whatever*. These decompositions may have been the occasion of much mischief, and hence opium, on which practitioners are used to rely as a protection, is on that account inadmissible. Care should also be taken to have the acetate very pure. The best preparation I have met with was furnished by Messrs. Preston, of Smithfield Bars, London.

Hospital Reports.

DEVON AND EXETER HOSPITAL.

CASE OF FRACTURE OF THE SPINE ADMITTED UNDER THE CARE OF J. EDYE, ESQ.

(Reported by W. CLAPP, Esq., House-Surgeon.)

Elizabeth Richards, aged 21, was admitted into the Devon and Exeter Hospital, under the care of Mr. Edye, on the 8th July, 1850, having just fallen from the top of a house, a height of about fifty feet. She was leaning against a wooden railing which surrounded the roof, when it suddenly gave way, and she fell into a paved court upon her right side. She was in a state of extreme prostration, almost pulseless, and only partially sensible, very restless, throwing about her arms and head, but her lower extremities were motionless. The right thigh was fractured a little below its middle. On moving her head she appeared to suffer extreme pain at the lower part of the back of the neck, was constantly desiring to have her posture changed, and especially to be raised in bed, and requested repeatedly that her legs might be rubbed. Respiration hurried, and appearing to be performed chiefly by the diaphragm. No vomiting. A cautious examination of her spine was made, but no fracture or displacement detected. A long straight splint (Liston's) was applied to her thigh. No retraction of the muscles had occurred. On account of her prostrate condition stimulants were given, and she was kept as still and quiet as possible. By the next morning some reaction had taken place. She complained of extreme pain about the lower cervical and first dorsal vertebræ, was capable of moving her arms, but all the parts below the mammæ were paralyzed, both as regarded motion and sensation, and no reflex action was developed. She had vomited once a greenish bilious fluid. No action of the bowels; and no urine passed. A pint of the latter fluid drawn off by the catheter.

On the 10th (two days after her admission,) the paralysis continued to the same extent, but her arms were moved apparently with more difficulty, and she complained of pain in them, but no numbness. Lower part of the neck extremely painful, both on her moving it and on its being touched, and extending downwards to

the upper third of the dorsal spine. Urine drawn off; no action of the bowels; nausea; had vomited once, the ejected matters and eructations having a most offensive fæcal odour; intellect quite clear. On the evening of the 10th her respirations became more rapid and jerking; pulse 95, of tolerable power; great heat of skin, and thirst; tongue white; repeated vomiting; abdomen much distended and tympanitic; pain excessive at the lower part of the neck; some numbness of the arms.

11th.—Prostration extreme, but she is still sensible; respiration more laborious, and jerking; repeated vomiting of matters of the same stercoraceous odour and character as before. An enema had been administered, but no action of the bowels produced. Abdomen rather less distended. In the evening she had somewhat rallied, but was very restless, and complained of her neck, and occasional cramps of her arms. Desired to have her legs raised, saying that she felt them, but was quite unconscious of their being touched, and no reflex movements were produced. Occasional vomiting, but not stercoraceous. An enema administered, without effect. A catheter introduced.

12th.—Paralysis the same, with severe cramps of the arms, and in a less degree of her chest also; abdomen tympanitic; bowels not yet acted upon; urine drawn off night and morning.

13th.—Cramps in her arms very severe; desired for the first time to have her urine drawn off, and said that her legs felt heavy, but she had no distinct sensation in them.

15th.—Bowels acted on for the first time since her admission by the aid of aperient pills, and copious dark and offensive motions produced; tympanitic distension of the abdomen entirely removed; the paralysis extends to a little above the nipples; requested that her urine might be drawn off, which was last night first observed to have an ammoniacal odour, but did not change turmeric paper; no crystals detected by the microscope, but some mucus and epithelial scales.

16th.—Free action of the bowels occasioned by the aperient pills had continued, the motions being passed unconsciously; since the administration, however, of an opiate enema, the diarrhœa has somewhat abated; no sensation below mammæ; no reflex movements.

17th.—Diarrhœa ceased; a superficial sore discovered on the nates.

18th.—Paralysis of arms increased, inability to raise them perfectly; extensor muscles of fore-arms especially affected.

24th.—Debility increased, and sore on the nates extending; urine for the last few days slightly tinged with blood, and containing a large quantity of mucus and crystals of triple phosphate; arms moved with greater difficulty, the left most so.

25th.—An undue projection of the spinous process of the cervical vertebræ observed, with a considerable depression immediately above it, and at this point most pain is experienced, especially on her moving her hand.

31st.—Fracture of thigh almost firm, and a considerable amount of callus thrown out, in size nearly that of one's fist; she has made no complaint of her neck for the last two days, but on the contrary stated her belief of being able to rotate her head, or raise it; aspect improved; sore on nates almost healed, but another has arisen on the upper part of the thigh, through the pressure of the fillet which confined the splint; urine more healthy, containing less mucus and phosphates, and no blood.

August 7th.—Not so well generally, but paralysis the same; pain in neck increased, probably owing to her head having been incautiously allowed to droop two days since while she was being removed to a fresh bed, and at which time she complained greatly of the seat of injury.

8th.—Fracture of thigh quite firm; callus considerable.

11th.—Splint removed, thirty-three days after her admission; limb shortened half an inch.

22nd.—Pain of neck much increased; no reflex motions of extremities.

September 5th.—General health declining; power of motion, however, of her arms rather increased, being able to raise them to her head, and again place them on the bed, especially the right.

8th.—Occasional severe pain in the neck, shooting up the back of the head; the slough over the sacrum has much extended, and affects her general health; debility and emaciation increased.

15th.—Placed on an India-rubber elastic bed, from which she says that she experiences great comfort.

October 2nd.—Pain in the neck still severe; debility and emaciation increased; paralysis extending to about two inches above the nipples; is unable to raise her left fore-arm, and the right only a little; respiration diaphragmatic.

November 8th.—The paralysis now extends as high as a curved line from the top of each shoulder, downwards across the chest about four inches above the nipples; below this the cuticle is of a yellow colour, dry, and brawny, and is thrown off abundantly by desquamation; the upper and lower extremities have also assumed this peculiar condition, and the growth of hair on them has also been unusually great; the sore on the sacrum has acquired a greater size, and ulceration also has taken place over the internal condyles of both arms, and over the scapulæ; debility and emaciation much greater.

December 6th.—Debility increasing, and nearly approaching to a state of syncope.

9th.—Sunk to day through mere exhaustion, (five months after her admission;) sores had also formed over some of the ribs, and the spinous processes of the third or fourth dorsal vertebra.

On a *post-mortem* examination eighteen hours afterwards, on removing the arches of the vertebræ, the sixth cervical was found to have been fractured through its body, and greatly displaced backwards, thus forming by its union with the fifth and seventh, to which it was firmly united by bone, a considerable angle over which the cord had been stretched, and its natural structure, to the extent of an inch, entirely destroyed, and con-

verted into a mere slightly reddened pulp. No laceration of the dura mater had occurred, but on being divided it was found adherent to the attenuated remains of the cord. The latter was examined as low down as the third dorsal vertebra, and to this extent was found to have undergone softening, and its grey matter to be indistinct and ill-defined. A more extended examination could not be obtained.

Of the treatment adopted where no otherwise than a fatal result could be anticipated, little need be said. The case, however, may perhaps be considered to possess some physiological interest, from the rapid union of the fracture of the thigh, and the abundant growth of hair, &c., upon the paralyzed parts, showing how readily the functions of nutrition and reproduction are performed, even where the spinal cord has undergone so severe a lesion. It may also be mentioned that the India-rubber bed, manufactured by "Matthews, of Charing Cross," and recommended by Mr. Luke, of the "London Hospital," appeared to be of much service, both in retarding the progress of the bed-sores, and in affording ease and comfort to the patient. Its superior lightness and portability will probably render it, in many cases, (especially in private practice,) a useful substitute for the more cumbersome and costly, yet invaluable, water-bed of Dr. Arnott.

Provincial Medical & Surgical Journal.

WEDNESDAY, JUNE 11, 1851.

Our attention has been directed to the circumstance that the University of St. Andrew has recently granted its degree of M.D. to a gentleman practising in Norwich as a professed homœopath, and whose name is registered as such in the printed list of these practitioners. There are some reasons why we should have preferred to take no notice of this unparalleled proceeding, but it would exhibit a sad want of respect to our valued correspondent as well as of duty to our constituents, did we allow any consideration whatever to interfere with our functions as conductors of this Journal. It may be a matter of surprise to many, as it was to us, that any conscientious believer in homœopathy should desire or consider it any honour to possess the diploma of an examining body which he knows must regard his favourite doctrine and practice with contempt or disgust, as it may chance to think them a folly or a fraud; but we must own to a feeling of something more than surprise, when we find an individual who professes to be honest in his convictions, not hesitating to suppress his real sentiments, and answering all the questions put to him, in such a manner as to lead the University authorities to imagine that they were about to bestow their degree upon a practitioner of rational medicine. Is not this something like obtaining a degree under false pretences? That the individual in question, Mr. Douglas Hale, did answer the queries in such a manner as to hoodwink the examiners as to his real character, we know to be the fact. Although as a homœopath, looking upon blood-letting with horror, and considering half a grain of antimony or a grain of calomel sufficient to dose the whole county in which he resides, he does not hesitate to recommend both antimony and calomel in the doses given by allopathic practitioners, when questioned as to the treatment of iritis, enteritis, or pneumonia. When such a dereliction of the first principles of conscience—not to say of manly candour, is forced upon us, we know neither acquaintance nor fellow-township. As conductors of a journal devoted to the defence of the honour and integrity of the medical profession, we feel bound to give such conduct our unqualified condemnation. It may be urged in extenuation, that the candidate believing the questions referred to the views of treatment ordinarily accepted, thought it right to shape his answer accordingly. But this is at least but a lame excuse, and does not remove the stigma of duplicity from which every honourable mind should recoil. However, this loophole for escape will scarcely avail, for we find in the third examination paper these damning words:—"The examiners expect that in the answers to the practical questions every candidate will specify *the mode of treatment he is in the habit of adopting, and the doses of medicines which he prescribes.*"

We here quit this painful subject as far as the candidate is concerned, with the addition that our pages are at his service if he be willing to show how his conduct can be reconciled to the principles of strict morality. But we demand of St. Andrew's for her own sake, as well as for the sake of her alumni, to take some notice of this mal-appropriation of her diploma. If, when other colleges are debating whether they shall not cut off these practitioners from their lists, as gangrened spots should be severed from the living flesh, she cannot show that her diploma has been given in error, she will have to submit to a degradation from which it will be hard for her to emerge.

While on the subject of homœopathy, we take the opportunity of expressing our concurrence in the apparent determination on the part of some of our London contemporaries, to convince regular practitioners that they do discredit to their own fame, and jeopardize the honour of their profession, by consulting with members of the homœopathic sect. There can be no doubt that the chief impulse has been given to this delusion, by the secession of the ill-informed and the unsuccessful from the ranks of legitimate medicine to join the disciples of Hahnemann, some from sheer ignorance of the principles of pathology, others from the more reprehensible motive of filling their needy exchequer, by pandering to the silly caprices of fashion. It is on this account the more requisite to set a mark on those practitioners, who, by meeting these people in consultation, *pro tanto* sanction their dogmas, or at the very least, lead the public to confound the true with the false in the practice of medicine. That the determination to make instances of this dishonest league known to the profession, is not an idle threat, is manifest from the fact that a London physician-accoucheur has been "shown up," in the *Lancet* for the fault alluded to, and we trust that no one will be spared whatever may be his professional standing. If the mass of practitioners be true to themselves this scandal must cease. Physicians or surgeons, however celebrated, who, for the sake of a few guineas, or from the contemptible "flunkeyism" that fears to disoblige a noble or wealthy patient, thus desecrate their calling, may be made to find to their cost, that other consultants are to be obtained of equal talent and more probity; and we do not doubt that if no more honourable motive should influence them, the *argumentum ad sacculum* will not be without its due weight in causing them to be more careful of their conduct.

Reviews.

Practical Remarks on the Treatment of Aneurism by Compression, with Plates of the Instruments hitherto employed in Dublin, and the recent Improvements by Elastic Pressure. By J. Tufnell, M.R.I.A., Fellow of the Royal College of Surgeons, Ireland. Dublin: Fannin and Co. London: John Churchill. 1851. 8vo. pp. 154.

In our review of Mr. Skey's recent work on surgery we animadverted on his remarkable omission of all allusion to the cure of aneurism by compression, as practised in Dublin with so much success. We think, therefore, we cannot do better than to show the nature of the operation which has been thus ignored by one of our metropolitan surgeons, together with its attendant success or failure, as evidenced by the results of the cases published. We will pass over the early part of Mr. Tufnell's remarks, which consist of a description of the disease itself, and a dissertation upon the claims of the various surgeons to whom the invention has been assigned. Mr. Tufnell gives the chief merit to Dr. Bellingham, although he admits that Mr. Todd tried the plan twenty years before, but unsuccessfully. We cannot, therefore, see what merit the former gentleman can lay claim to, further than the comparative success of his operation; as until the addition of the elastic medium afforded by vulcanized Indian-rubber, the pain was so great as to render the operation almost useless. If, therefore, Mr. Todd is to be deprived of the honour of the discovery we should certainly assign it to Dr. Carte, who first suggested the introduction of the elastic bands of caoutchouc. The following are the conditions which are now considered in Dublin as necessary for the success of the operation. Mr. Tufnell says at page 45:—

"I *consider compression applicable* to every ordinary circumscribed Aneurism in an extremity, where there is sufficient room for the application of the compressing medium at two different points above the tumour, premising, of course, that pressure on the trunk of the vessel completely controuls pulsation in the sac, thus proving that no high bifurcation exists.

"*I do not advise* it in cases which are rapidly extending in size, or where they continue to do so after compression has been tried. These Aneurisms have no distinct sac; and to afford any chance of saving the limb, the blood through the main channel *must be cut off, and at once*, by securing the vessel.

"*I do not advise or sanction it* in cases where the disease has been allowed to run on unchecked, where the limb has become œdematous and swollen, and the surface of the Aneurism a dusky, yellowish red. In such a case the vein is most probably engaged, and, if it be a popliteal Aneurism, the knee-joint inflamed. Here, I believe, amputation is the only resource.

"Understand me, then: compression I advocate only in cases where the sac is entire, and where sufficient room exists for applying the pressure on two points of the artery above. At the same time, cases have so frequently occurred where the application of a single instrument has been sufficient for a speedy cure, *(such, for instance, as one that I saw under the care of Dr. Hutton, where popliteal Aneurism of a considerable size was in seven and a-half hours, by means of a*

single instrument, constructed on Dr. Carte's plan, rendered completely solid,) that, although, for prudence sake, *and as a general principle*, I advocate the employment of two points of pressure, yet, I by no means hesitate to employ a single instrument, and give the patient every chance, prepared at the same time to use the ligature if any necessity arise."

Our author next treats of the preparatory treatment which is necessary to bring the general circulation of the patient into such a state as shall reduce the necessary pressure to the lowest possible amount, consistently with such a state of health as shall enable the skin to bear the apparatus without the risk of gangrene supervening. All this is highly necessary in practice; but as the means will suggest themselves to every intelligent surgeon, we shall pass on to the selection of the instrument.

Mr. Tufnell gives an account of all the varieties of apparatus which have been employed, illustrated by engravings, which though not of a very high artistic value, are yet sufficiently good to shew the nature of the various machines. From these he makes choice of the apparatus invented by Dr. Carte, the chief merit of which consists, as we before observed, in the application of vulcanized Indian-rubber, instead of the fixed pressure of the screw; this pressure, however, is still *regulated* by a screw, somewhat after the fashion of the ordinary tourniquet. In the application of this machine there are, of course, many niceties involved: but here we will allow Mr. Tufnell to speak for himself. He says—

"If you act as I advise you, you will find, perhaps, that two or three hours elapse before the patient feels annoyance from the pad. Do not wait, however, for him to make complaint of pain, but, as soon as uneasiness is felt, let the thigh apparatus (which should have been already loosely applied) be brought into play. Experience will soon tell both the surgeon and patient, how far the compression need be carried in order to command the circulation before the pressure on the groin is relaxed. This done, and the pulsation in the tumour found arrested, reverse the screw little by little till a *feeble wave* in the Aneurism can be felt. Then take one whole turn forward, and the circulation will be fully controuled. Let the following then be your guiding rule: where no contraindication exists, *make your command over the circulation complete, but do so with the minimum amount of pressure by which this object can be gained.*"

With regard to the results of the operation, a table is given of thirty-nine cases treated in Dublin, from October, 1842, to March, 1851. In thirty of them the cure has been perfect and complete; in one compression was discontinued, the aneurism remaining stationary; in two the ligature was subsequently applied, with success; in three amputation was required, followed by recovery; in one death ensued from erysipelas; and two died from co-existing disease of the heart. Mr. Tufnell analyzes all the unsuccessful cases, and endeavours to shew that they ought not to be allowed to deter any one from the operation, since there were unfavourable circumstances attending them all. And this would be allowable if there were no opportunity of comparing the relative mortality of this operation with that occurring after tying the artery; but as we have ample opportunities of doing this, and as Mr. Tufnell himself has adduced the tables of Crisp, Phillip, and Norris, it is quite needless, and indeed unfair, to examine individual cases in the one list without doing the same in the other. But still the success is greater in the cases of compression than in either of the lists above alluded to, in which, on the average, nearly one in three were unsuccessful. The importance of this comparison can scarcely be over estimated. There is, no doubt, some mechanical skill necessary for the proper application of the instrument; but in so serious a matter nothing ought to prevent our adopting every means presented to us for diminishing the danger of so severe an operation as the deligation of the femoral artery. We trust that the plan will have a fair trial in this country; but if the London hospitals are to be closed against a method apparently so simple, we are sure that the surgeons of our provincial institutions will do their duty by fully investigating the claims of this bloodless process to supersede the necessity for the Hunterian operation.

Proceedings of Societies.

DORSETSHIRE BRANCH.

The second meeting of the Dorsetshire Branch of the Provincial Medical and Surgical Association was held at the Dorset County Hospital, Dorchester, on Tuesday, the 20th ult. There were present—Dr. Cowdell, T. Salter, Esq., G. Curme, Esq., R. Fooks, Esq., E. O. Spooner, Esq., H. A. Arden, Esq., J. Wallis, Esq., R. M. Rendall, Esq., J. F. Coles, Esq., J. Corey, Esq., J. Edwards, Esq., A. Emson, Esq., F. Goldsmith, Esq.

The chair was taken at one o'clock by Dr. Cowdell, the President, who, in a brief address, alluded to the present prospects of the profession in regard to the

long and much vexed question of Medical Reform, as affording a hope that the concessions of the College of Surgeons, and the highly improved curriculum of the Apothecaries' Company in the requirement of a high standard of preliminary education, would in a great measure satisfy the demands of Medical Reformers. Dr. Cowdell especially adverted to the importance of this last act of the Apothecaries' Company, at the same time expressing his belief that the profession is under deeper obligations to this than to any other licensing body. Dr. C. then glanced at the most important improvements in the practice of the profession during the past year, which has not been very prolific in this respect. The President urged upon the members of the Association the importance of continued individual and combined exertions in its behalf, exhorting them not to be discouraged by the great apathy evinced by too many medical men, and expressing a hope that better days and a better spirit would ere long appear. Dr. Cowdell alluded, *en passant*, to the unpleasant difference which had, soon after the last annual meeting, taken place between several members of the Association and the Dorchester Board of Guardians; and, in consequence of the painful division to which that occurrence had given rise among his medical neighbours, he suggested that the Association should on similar occasions assume the duties of an Ethical Society, and that the Council should appoint a committee of its members to act as referees.

An interesting paper "On the Acetate of Lead," by W. Sweeting, Esq., of Abbotsbury, was then read. (This paper is published at page 320.)

A short but animated discussion on Mr. Sweeting's paper took place, the opinions, strongly supported as they were by facts, being opposed to the general belief of the profession.

Mr. Salter next read a paper "On Intussusception," illustrated by cases, (one of them of unusual interest,) as also by pathological preparations.

The President next drew the attention of the members to a "Case of Uterine Irritation," in which, after a long unsuccessful treatment, a rapid and perfect recovery took place under the use of the cannabis indica.

A vote of thanks was then passed to each of the authors of the papers, and after inspecting the wards of the hospital, and paying a visit to the County Museum, the members retired to the Antelope Hotel, where a dinner was provided.

After the usual loyal toasts the report of the District Secretary, Mr. Spooner, was read. The points of local interest upon which this report commented were the Dorset Friendly Society and the Dorchester Board of Guardians. The present hopeful state of the Medical Reform question then passed in review. In some future number we hope to present an abstract of this report, which called forth expressions of cordial unanimity and satisfaction from all the gentlemen present.

In consequence of the time of the meeting precluding the reading at length of two papers by Mr. Spooner, one in continuation of the vaccination and post-vaccine inoculation paper, which we published in our number for July 10th, 1850, the other "On the Pathology of Ague," an extemporaneous summary of their contents was sketched by the author, which gave rise to an agreeable discussion, in which several members present joined, till the hour of departure arrived. The re-appointment of the council and officers of the branch concluded the business matters of the Association, and a hope was generally expressed that the Council would call another meeting previous to the anniversary in May next. It was considered that if possible, an autumnal meeting would be desirable, but it was left to the discretion of the council to decide as to the propriety of such meeting, which would depend much on the urgency of topics of local or general interest at that season of the year.

EPIDEMIOLOGICAL SOCIETY.

The following circular of the Epidemiological Society is reprinted in consequence of an omission of a portion of the questions in our last number:—

SMALL POX AND VACCINATION.

Dear Sir,—A Committee of this Society is now engaged in investigating the important facts connected with Small Pox and Vaccination, and they are desirous of obtaining information from every authentic source. It will be in your power to render them most valuable assistance if you will kindly furnish them with answers to any or all of the following questions; and I beg to assure you that the information you thus afford will not only be most thankully received, but will be carefully acknowledged in the Report which it is the intention of the Society to publish. I hope that it will be convenient to you to return this paper before the first of July next.

I am, dear Sir,
Your obedient Servant,
B. G. Babington, President.

1. Have you any record of the cases of Small Pox, which have fallen under your observation whether,
   a, Natural.
   b, After a previous attack of Small Pox, or
   c, After Vaccination,
   and if so would you state the number of each kind and any particulars you may be acquainted with, especially with regard to the ages of the patients and the character of the attack in each class of cases.
2. What has been the mortality in each class that you have specified, and in how many cases, *especially in those after Vaccination*, could the death be fairly ascribed to Small Pox, or to previous, coincident, or superadded disease?
3. In each case of Small Pox after Vaccination, how long a period had elapsed since the performance of the Vaccination?
4. In cases of Small Pox, presumed to be after Vaccination, what was the evidence of the Vaccination having been effective?
5. Have you any facts to show that the protective or modifying power of Vaccination bears any relation to the *number* of genuine cicatrices left by the operation?

6. Have you *seen* the Vaccine Disease, and subsequently Small Pox, occur in the same individual, and if so, in how many cases?
7. Have you ever had an opportunity of watching an Epidemic of Small Pox from its outbreak to its termination, and would you favour the Society with the result of your observations? The Committee are desirous of being informed whether the disease first appeared among the resident inhabitants of the district, or whether it was imported, or produced *by Inoculation?*
8. Have you any evidence of the spread of Small Pox from the improper exposure of persons labouring under the disease?
9. In what manner are you in the habit of performing the operation of Vaccination? How many punctures or incisions do you make? In a person whom you have Vaccinated, what are the tests which satisfy you that the Vaccination has been effective?
10. Are you in the habit of omitting to Vaccinate in the winter, and, if so, for what reasons?
11. Are you able to maintain a supply of lymph? If not, how are you supplied? Have you (at any time) experienced difficulty in obtaining lymph when required?
12. Have you ever seen any anomalous effects follow Vaccination, or anything to support the notion that other diseases may be introduced into the system through Vaccine lymph?
13. Have you ever vaccinated directly from the Cow, or known any one so vaccinated, and with what results?
14. In how many cases have you re-vaccinated? what were the results of the operation? what evidence had you in each case of the former Vaccination having been effective? Have you any facts in proof of re-Vaccination affording additional protection from Small Pox?
15. By any inquiries you have had occasion to make on the outbreak of Small Pox have you ever been able to ascertain, or could you now ascertain, the number of unvaccinated persons in your town, parish, or district?
16. Have you known instances in which Vaccination of all the inhabitants of a village or district has prevented the epidemic visitation of Small Pox, although it prevailed in adjoining places? and if so, will you state the exact particulars?
17. What have you found to be the principal obstacles to Vaccination being universally practised, and can you suggest any plan for insuring the Vaccination of every person throughout the kingdom?
18. —Have you *yourself* been Vaccinated, and at what age? Are there any cicatrices visible; and if so, what is their number and character? Have you been re-Vaccinated, and with what effect? Have you been frequently exposed to Small Pox? Have you taken Small Pox—and if so, what period had elapsed since the Vaccination and since the re-Vaccination?

THE STOCKPORT MEDICAL SOCIETY.

TESTIMONIAL TO DR. TURNER.

This Society, though it has, we believe, been established two years, and includes in its list of members most of the leading practitioners resident in Stockport and the immediate neighbourhood, has conducted its operations so unostentatiously, that we had scarcely heard of it, and should not probably even now, had not its second anniversary meeting been thought a favourable opportunity of presenting Dr. Turner, under whose auspices the Society was founded, with some mark of their esteem for his long and unwearied exertions in the cause of suffering humanity, and for his unvarying kindness and urbanity in his intercourse with his professional brethren, which rendered a more public notice necessary.

This idea was no sooner hinted at, than cordially embraced by the members of the Society, and other medical friends of the Doctor, resident in or connected with Stockport; and at a meeting called to consider the best mode of testifying their regard for their distinguished associate and friend, it was agreed upon to present him with a handsome silver inkstand, with a suitable inscription engraved thereon, and an address on vellum, more fully expressing their feelings, to be signed by each contributor to the plate; and that it should be presented at the anniversary dinner of the Society, on the 24th of April. A sub-committee was appointed to carry out these intentions, and we understand the result of their labours was highly gratifying to all the subscribers, (twenty in number.)

Accordingly, on Thursday the 24th of April, the subscribers to the testimonial, with the exception of three or four who were prevented by professional engagements, sat down to an excellent dinner at the Wellington Bridge Hotel, the chair being occupied by Mr. Medd, President, and the vice-chair by Dr. Rayner, senior Vice-President of the Society.

The company consisted of Dr. Turner, who sat on the right of the Chairman; Mr. Downs, Mr. Brooke, Mr. Bellott, Mr. John Rayner, Mr. Blackshaw, Mr. Massey, Mr. Bowring (Manchester), Mr. Thomas Cheetham, Mr. John Howe (Marple), Mr. Wm. Lowe, Mr. Walters, Mr. J. Brooke, and Mr. James Rigby, House-Surgeon to the Infirmary and Hon. Secretary to the Society.

The usual loyal toasts having been proposed and responded to with becoming enthusiasm, the Chairman next introduced the toast of the evening, with some very appropriate remarks, and concluded by observing that the eulogium he had ventured to pass upon his friend, Dr. Turner, in his presence, was already more than verbally assented to by those before whom he had the honour to speak, by their having delegated to him the very pleasing duty of offering to the Doctor this proof (here presenting the inkstand) of their high opinion of his worth, backed by the address, to which they all had subscribed their names—an expression of regard, not given merely to his official distinctions, but to his character as a Christian, a physician, and a gentleman.

The Chairman here read the inscription, which was

very neatly engraved on the inkstand, and ran as follows :—

"Presented to George Turner, M.D., Mayor of the Borough of Stockport, Senior-Physician to the Infirmary, First President of the Medical Society, &c., by his professional friends, as a slight Memorial of their high respect and esteem. April 24th, 1851."

The Chairman then read the following address (on vellum) :—

"To George Turner, M.D., Mayor of the Borough of Stockport, Senior-Physician of the Infirmary, First President of the Medical Society, &c.

"Sir,—We avail ourselves of the opportunity afforded by the anniversary of the Medical Society, to request your acceptance of the accompanying inkstand, as a token of our regard. As such we feel assured that, although its intrinsic value is small, it will not be the less appreciated by you when you perceive, from the following signatures, that it is not the gift of two or three individuals, but of a considerable number of those who have had the pleasure for years of admiring your professional attainments, kindness, and urbanity, enjoying your private friendship, and esteeming your moral worth and Christian character. That you may long be spared in health and strength to continue your valuable labours in aid of suffering humanity, and to assist, as you have ever done, in promoting that amity and good feeling which ought always to characterise the members of a liberal profession, is the earnest wish of

"Your medical friends,

"John Medd; W. Henry Bellot; John Rayner; Chas. A. Walters; Thomas Cheetham; James Ashton, M.D.; Thomas Cooper Leah; John Brooke; John T. Pearson; George Bowring; William Rayner, M.D.; George Downs; Thos. Massey; Wm. Lowe; George Young Graham; Isaac Brooke; Joseph Blackshaw; John Howe; A. Thom Thomson; James Rigby."

Dr. Turner, on receiving these assurances of friendship and esteem from so many of his professional brethren, and so unexpectedly, appeared very much affected, and on rising to reply, said he never knew a secret so well kept in his life, for until that moment he had not the least idea of the honour intended him. After thanking them for this very unexpected mark of their kindness and good will, which he did in very eloquent and feeling terms, he descanted upon the great and numberless advantages arising from societies of this description, both to the members composing them, and to the public; and concluding by proposing, in very flattering terms, the health of the President. Some other routine toasts were given, and the party, which was of a most harmonious and pleasurable character, separated about half-past ten o'clock, highly gratified with the evening's proceedings.

Our readers will not, we think, be uninterested in this Society, especially such as are resident within its influence, when they learn that its objects are to encourage a friendly intercourse among its members, and to promote the increase of medical science generally, by conversation and discussion on short dissertations on select subjects in medicine and surgery, the exhibition of pathological specimens and prepartions, new books, instruments, &c., &c., by which means such a degree of knowledge and interest in the profession is kept up in the members, as cannot fail to lead to very beneficial practical results.

Foreign Department.

PROCEEDINGS OF THE FRENCH ACADEMIES.

ACADEMIE DE MEDECINE.

M. Bouillaud reported on a memoir by M. Homolle and Quevenne, "On *Digitaline*: the active principle of the Digitalis Purpurea." Speaking of his own experience of its effects, M. Bouillaud stated that he had tried it in nervous affections of the heart, as well as in organic diseases of this organ and the aorta, and also in intermittent fever. In 150 or 200 cases the medicine, in all but three, produced a notable diminution in the frequency of the pulse. In the discussion which followed, MM. Rochoux and Delafond called attention to two points, viz., the fact that in febrile affections digitalis increases rather than lowers the pulse; and to its action on the kidneys and the respiration.

An elaborate essay on "*Arterial Varix of the Scalp*" has been presented by M. Robert. The occasional causes of these affections are few, two only being at present known, namely, contused wounds and congenital sanguineous tumours; the latter towards puberty often increase rapidly, and the singular affection known as cirsoid aneurism develops itself. Its progress is at first slow, but sometimes it proceeds with wonderful rapidity. The diseased part becomes larger, and the skin assumes a peculiar brownish or purple discoloration; or, in some cases, the skin is not altered, except in getting gradually thinner, so as to allow the enlarged vessels to be visible. In this case the tumour presents numerous irregularities, resembling varicose veins. On placing the hand on the tumour an expansive movement isochronous with the pulse is perceived, together with a strong vibratory thrill. Both the thrill and the pulsation are diminished by pressure on the carotid. Around the tumour the blood-vessels are large and tortuous.

Left to itself cirsoid aneurism has always a tendency to increase, and eventually gives rise to alarming hæmorrhages, by rupture or ulceration. The diagnosis is easy when it follows upon an erectile tumour, but when it arises either spontaneously or consequently to a blow, it may, according to M. Robert, be confounded with aneurismal varix. The treatment is not encouraging; hitherto the author has never known a permanent cure effected. Ligature of the carotid may retard its progress, but the collateral circulation soon restores the disease to its prior condition. As a last resource he counsels ligature of both carotids.

In discussing the contents of the essay, M. Cloquet denied the universally fatal progress of the disease, and mentioned the case of a Spanish nobleman in whom it

was cured spontaneously. M. Velpeau held the same opinion as to its occasional fortunate termination.

M. Lisle read a memoir "*On the Influence of the Seminal Losses on the Production of Mania.*" The deductions which he draws from his own observations are to the effect that insanity from this cause has peculiar features which are readily recognised, and that though it resist all ordinary treatment, speedily subsides after the spermatorrhœa has been arrested.

Treatment of Lupus by the Topical Application of the Bi-ioduret of Mercury.

M. Cazenave, (*Annales des Maladies de la Peau*) after trying a variety of local applications in lupus, has come to the conclusion that none is more efficacious than the bi-ioduret of mercury. After a certain number of applications of this drug, with the transient local inflammations which it excites, he has seen the hypertrophied tissues, as it were, dissolved, the tubercles disappear, and soft cicatrices form. He has, in fact, seen the most repulsive cases heal, with no more disfigurement than arises from a patchy discolouration of the integuments.

The application is not in general painful at first, but it is soon followed by severe suffering, which lasts from six to twelve hours. The pain is accompanied by erysipelatous redness of the parts adjacent; but the redness and swelling subside in three or four days. The iodide of mercury then forms a crust with the exudation which it occasions, and on falling off displays a smooth cicatrix. The same effects follow the application to lupoid ulcerations.

The bi-ioduret of mercury may be dissolved in ether, incorporated in an ointment, or suspended in oil. M. Cazenave prefers the latter. As the application is painful and requires to be repeated for five or six days, he recommends that only a small space should be touched at once.

Ovariotomy, by Small Incision and Puncture of the Cyst.

A successful case of this operation is recorded by M. Knorre in the *Gazette Médicale de Strasbourg*. There was nothing peculiar in the case or in the operative proceedings, and the patient recovered without a bad symptom. The cyst was unilocular, and had contracted slight adhesions.

Volvulus Cured by Gastrotomy.

Volvulus, whether arising from internal strangulation or invagination, is commonly considered beyond the reach of art. Such at least was the opinion until the operation of gastrotomy was performed. In the following case, by M. Reali, (*Revue Medico-Chirurgicale* Janvier, 1851,) it was successful, although the recovery of the patient was impeded by wounding the intestine and the necessity for sutures, which probably induced the excessive suppuration spoken of.

The patient was a peasant, aged 30, a robust man, but the subject of hernia. After severe exertion he was suddenly seized with pain across the lower belly, soon followed by vomiting and obstinate constipation. All the symptoms of ileus speedily supervened; and the operation of gastrotomy was resorted to as the only chance of relief.

Having inhaled ether, which did not, however, altogether succeed, an incision was made in the median line, from the umbilicus to the pubes. The hand was introduced into the abdomen in the direction of a tumour which had previously been perceptible in the right iliac fossa. This tumour was then found to consist of a portion of the ileum, so twisted upon itself as to enclose and strangulate a portion of bowel. As the knot could not be unravelled, the operator made three incisions into the distended gut, which enabled him to overcome the difficulty. When the gut was unravelled, the three incisions were found to be united in one longitudinal cut, which required the interrupted suture. The edges of the external wound being brought together, cold compresses were applied, and nothing but cold water was allowed to be taken internally.

The vomiting and hiccup ceased soon after the operation, and on the second day the bowels were freely relieved. Subsequently the wound was attacked with erysipelas, and a copious suppuration, with sloughing, occurred. On the twentieth day the suppuration ceased, and the wound speedily cicatrized.

General Retrospect.

ANATOMY AND PHYSIOLOGY.

On some Peculiarities of the Sphenoid Bone.
By Dr. Neill.

Dr. Neill called attention to certain peculiarities of the sphenoid bone not described by anatomical writers. In the description of the bone given in the books, we are told that the pterygoid processes project downwards perpendicularly, which may be the case in a large proportion of the skulls of the European races. If, however, he informs us, we examine a variety of specimens, we shall find that the perpendicular direction of the pterygoid processes does not invariably prevail. Thus, in the African, they are very oblique, running nearly parallel with the oblique line of the face. In the Mexican skull they are very nearly vertical. There will very generally be found a parallelism between the direction of these processes and the line of the face. In the fœtus they have the peculiar obliquity of the face; and in all races, the nearer the characteristics of the adult head approach those of the fœtal, will the direction of the pterygoid processes be found more oblique. Dr. Neill was not aware that the fact just stated had any important practical bearing; the direction of the pterygoid processes will, however, have some influence upon the direction of the posterior nares, of

which it is important that the surgeon should be aware. The more oblique the processes, the more oblique will be the posterior nares, which follow, of course, the direction of the former.—*American Journal Medical Science*, January, 1851.

PRACTICAL MEDICINE AND PATHOLOGY.

Citric Acid in Rheumatism.—By Dr. Owen Rees.

When some time back Dr. Rees introduced lemon juice as a remedy for acute rheumatism, the salt of potash was considered the active agent, and it was thought that the same effects would not follow the exhibition of pure citric acid. Dr. Rees has, however, on trial found that such is not the case, but that, contrary to expectation, the disease is amenable to the acid treatment, though the convalescence is less speedy than with lemon juice. He thinks either far preferable to colchicum.—*Lancet*, May 24.

On the Venous Murmur.—By Dr. Ogier Ward.

Venous murmurs are stated by the author to be of two kinds, the continuous and the remittent. The former is heard in solitary veins, as the external jugular; the latter in the venæ comitantes of an artery. The general opinion is, that these murmurs are confined to persons of feeble constitutions, or who have been weakened by losses of blood. Hence it is met with universally in anæmia and chlorosis. Dr. Ogier Ward, however, having remarked the frequency of the venous murmur in children, whether anæmic or florid, was induced to make a number of observations upon them, and the result that he has obtained is, that *all children, male or female, under the age of seven years, exhibit the venous murmur.* Above the age of seven or eight years it begins to cease in boys, but in girls it generally continues till after puberty and the establishment of menstruation, whether the person be pale or florid. The author has not been able yet to establish the average period of its cessation, either in boys or girls; but from the frequency of its occurrence in adult young women, he believes that a very slight derangement of the general health is sufficient to produce it in them. The greater proportion of water in the blood, both of children and females, he considers a satisfactory explanation of these facts. There is, however, so great a discrepancy in the analyses of the blood taken from such patients, that no exact limits can be assigned to the variations, consistent with the health of the individual, as determined by the presence or absence of the venous murmur.

From these statements, Dr. Ogier Ward considers it evident that, with the exception of children, the existence of venous murmurs offers a pretty sure guide to the diagnosis and treatment of various diseases attended with a change in the condition of the blood. In the adult the author has never met with a case in which tonic remedies were not useful, especially iron, unless the patient laboured under some form of disease that counteracted its influence. The selection of the preparation of iron best adapted to the case must be guided by observation of the attendant symptoms.—*Medical Society of London, April* 26.

Symptomatic value of the Metallic Click.

Dr. Ormerod gives the following account of this sign:—

Occasionally there may be heard over the region of the heart a very peculiar sound, to which the name of metallic cliquetis, or tinnitus, or costal percussion, has been applied. In the interpretation expressed by the use of the last appellation, both Hope and Bouillaud agree; and Hope gives some details explanatory of the mode in which the sound appears to him to be produced. Laennec explains the occurrence of this sound in the same way by costal percussion:—"When the heart, beating in a sharp and rapid manner, though without any really forcible impulse, the apex only comes to strike the walls of the chest." Now, obviously, this explanation is somewhat shaken by the fact that this peculiar sound—which there can be no question about, for any one may produce it quite pure for himself in the way specified by each of these observers—is not always audible at the apex in cases where it may be heard at the base of the heart. Dr. Hope correctly remarks that thin nervous persons are the most common subjects of it, but they are not exclusively so; and this fact again impairs the general applicability of the details of his explanation. The sound may be, and the author believes is, trivial, and almost wholly unimportant; but, for all that, we need not accept a wrong or an unduly limited explanation.

Dr. Ormerod has met with it under four different conditions:—First, in nervous anæmic subjects, when the action of the heart was sharp; secondly, with more violent action of the heart, under circumstances which have led him erroneously to conclude, from the third condition with which he has less frequently found it connected, that it was indicative of the commencement of pericarditis. The fourth condition with which it has been found connected, is a rough, almost scaly, state of the pericardium about the base of the heart; and perhaps a fifth might be subjoined, but for the fact that it is not always constant under these circumstances:—namely, adhesion of the pericardium, with which we may class the occurrence of this sound over an aneurism. Dr. Latham assures the author, that he frequently meets with it in children, in whom he has noticed that it may be entirely suspended by a little pressure on the walls of the chest.

He asks:—What should be the conclusion from these facts? His reply is, that the explanation by costal percussion is insufficient, as it does not take in all the cases. The explanation by affection of the pericardium again is insufficient, though certain as far as it goes; yet there is positive proof in the continuance of the sound after adhesion has taken place, that the explanation does not go all the way. He concludes that there is no explanation that will include all cases.—*Medical Gazette*, March, 1851.

Physiognomy of Cardiac Disease.

In a further part of his lectures Dr. Ormerod observes, that in many diseases all distinctions of age are merged as regards the physiognomy; but it is not so with disease of the heart. This has its peculiar impress, both in childhood and mature age.

In children suffering from valvular disease of the heart, the face and conjunctiva are pale and bloodless. Only, through the unusually transparent skin, small vessels may be seen ramifying over the malar eminences and the alæ of the nose, and the face becomes dusky on any exertion or emotion. The features are full, not pinched, as in most of the chronic diseases of childhood. There is no expression of anxiety. With the eyelids partially closed, and the eyes turned down, they sit motionless, save for the constant heaving of their chests, and even of their whole bodies, with the beating of their hearts. Sad experience has taught them which posture is the freest from suffering; and this they steadily maintain, either upright, with the head leaning a little forwards on the chest, or, as the disease advances, reclining back so as to extend the trachea to the utmost: doubtless, on account of the relief which they thus afford to some labouring organ. They are sensible and intelligent often to a remarkable degree, like other children who have suffered much from sickness—and seem to take pleasure in being ausculted and made objects of attention. But as soon as they are left to themselves their eyes fix again upon some object, and they lie looking at it without apparently noticing it, like figures in wax.

The expression is quite different in persons of more advanced age; it is no longer one of placid quiet, but of anxiety and pain. There are still the same constrained unnatural postures, and the same fixed yet vacant gaze; but the face is drawn and livid, the lips are blue and pinched, the cheeks are of a dusky purple, and wherever the skin is put upon the stretch by subjacent parts, vessels may be seen ramifying just beneath the surface. Commonly the skin hangs in a fold from the lower eyelid, so as to expose the dull dingy conjunctiva covering the sclerotic; bloodless indeed, but wanting that pearly white which we see in anæmia. Much as bronchitis has to do with the sufferings of these patients, and with these particular appearances, yet attentive observation will recognise here quite a different expression to what we see in connection with that disease. There is neither the intense restless agony of the present attack nor the passive endurance when the acute stage of bronchitis is past. But to an expression which might suit with the most urgent distress and despair, there is joined a quietude of demeanour which might betoken perfect resignation. In all the patient's distress and uneasy movements, the great object of his efforts is to maintain the most complete rest; as if it were a question whether to bear the present posture, or the wearying search after one more tolerable to his feelings, were the greatest misery. "He cannot be at rest, for rest brings him no relief; he seeks but in one to be freed from the feeling of another pain."

SURGERY.

Tincture of Cantharides in Obstinate Ulcers.—By John Tait, Esq.

Mr. Tait speaks of a poor man who placed himself under his care for obstinate ulceration of the right leg of eight months' duration. On examination the integument from the knee to the ankle was a continuous mass of ill-conditioned ulceration, from which an offensive watery discharge issued. The ulcers were deep and scooped out, and had an irritable aspect. He first took Grey powder, quinine, and opium, which were continued till the gums were affected. Upon this the tumefaction of the limb subsided to a considerable extent, and more so after the subsequent exhibition of iodide of potassium, combined with a stimulating local application. Still the ulcers did not show any disposition to granulate, and the patient was therefore ordered to take ten minims of tincture of cantharides with each dose of the iodide of potassium. Three days afterwards the ulcers began to contract, and healthy granulations sprung up. The tincture was continued, with the balsam of peru in ointment, and in a fortnight cicatrization was complete.—*Lancet*, May 10, 1851.

On Strumous Urethritis.—By Dr. S. Wilmot.

The symptoms of this affection, as given by the author, are constant discharges of thin whey-like fluid, and scalding on micturition. These symptoms are increased by drinking spirits, sexual intercourse, or exposure to wet, cold, and fatigue. In some cases acute inflammatory symptoms ensue without obvious cause. If the patient be questioned, he generally states that he never had gonorrhœa, or so long ago as to preclude the idea that the symptoms are connected with it. On examination of the urethra, the first thing which attracts notice is a pouting of the lips of the orifice, which is not circular, as in gonorrhœa, but appears as if flattened laterally. The mucous membrane, as far as it can be seen, is highly vascular and panular, resembling what is known as a granular condition of the conjunctiva. The same condition probably extends throughout the urethra.

Dr. Wilmot regards this affection as essentially strumous, and believes that it is frequently the result of gonorrhœal gleet. If allowed to proceed unchecked, the bladder often becomes engaged, its irritability is increased, and it secretes pus.

The urine in general is neutral, its colour is of a slight milky hue, and a slight albuminous deposit will often occur. The albumen may arise simply from the admixture of pus with the urine, or it may be the consequence of renal disease. To determine which of these is the true origin, Dr. Wilmot passes a catheter into the bladder, and examines the urine drawn off. This proceeding excludes the mixture of pus from the urethra.

The treatment recommended is the occasional introduction of a bougie smeared with some astringent ointment. He also employs stimulant and astringent injections. The constitutional treatment must be anti-

strumous, as iodide of iron combined with extractum conii, nitro-muriatic acid in sarsaparilla, and sea bathing. Balsams and turpentine aggravate the complaint.—*Dublin Quarterly Journal*, February, 1851.

MEDICAL JURISPRUDENCE.

Death by Lightning; Rigor Mortis.—By Dr. F. J. Brown.

The chief interest in this case consists in the presence of *rigor mortis*—a phenomena which is generally supposed never to be observed in the bodies of those who are killed by lightning. The person killed was a sailor, and the accident occurred on board a barge which he was navigating in the Medway. On examination the lower portion of the left ear, and the entire left side of the neck, were of a purple colour. Over the epigastrium was a blistered patch. Red stripes covered the fore-part of the abdomen. *The body was rigid.*—*Medical Gazette*, May 16, 1851.

Correspondence.

SEXAGENARIAN THOUGHTS ON THE PRESENT STATE OF THE MEDICAL PROFESSION.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—Your correspondent "S.," in the *Journal* received this day, has most grievously mistaken his man if he fancies the sexagenarian to be one dreaming in his easy chair, and indulging your readers with *his speculations*. His observations have been drawn from facts: in the person of his son, he has lived among *the young men of the present day;* he is intimately acquainted with some of the most celebrated grinders of the day, and he has a large circle of acquaintance among those who are occupied in teaching. In fact, he has had the best opportunities of judging from facts; and he reiterates the assertion, that the examination *at the Hall* is the great bugbear to the student, compared with which that of the College is considered as slight and trivial—requiring far less accurate preparation. With regard to the former being *superficial*, while that of the latter is *deep, facts prove the contrary;* and the result upon which your correspondent S., relies, as supporting his view of the case—viz., the great number of *rejections*, in fact only proves the soundness of my assertion: the one is prepared for with care and diligence, the other is thought comparatively unimportant, and therefore is attempted carelessly and often unsuccessfully; the result proving, not the stringency of the examination, but the thoughtlessness of the student. The habit of "grinding" is a *very bad one*, but with a good memory, is equally applicable to *anatomy* as to other branches of our science; and here again I speak from facts in my own knowledge.

Celebrated men often make incautious or absurd assertions: such appears to be that of your correspondent's friend, that "a Frenchman would write a work in three folio volumes on a *flea's leg*." I once heard a most celebrated—*the most celebrated* surgeon of his day—and an intimate friend of mine, *boast* that "*he never read a book.*" *But is, therefore, reading to be despised?* I cast my eye from my table along the shelves of a large professional library, and when I see there the books of Petit, of Boyer, of Delpech, of Dupuytren, of Velpeau, of Vidal, and others, in surgery; of Baudelocque, Gardien, Capuron, Boivin, Lachapelle, Maygrier, and others in midwifery; of Bichat, Magendie, Geoffroy St. Hilaire, Cabamis, Virey, and others, in physiology; of Chomel, Broussais, Boisseau, Alibert, and others, on fever; of Prost, Louis, Rayer, Andral, Recamier, and others, on pathology; of Orfila, Foderé, Capuron, Chussier, Boer, and others, on medical jurisprudence—I become weary of selection—and I ask, is it possible for any one *who knows* the treasures of French and German medical literature to style it under the depreciatory epithet of so much "*verbiage?*" *and I reply, it is impossible*, proved also by the fact, that your correspondent evidently is not acquainted with these treasures. *He is* a young man, and your sexagenarian correspondent, who is himself a literary man, earnestly recommends him to obtain such an intimate acquaintance with French, as shall enable him to judge fairly *of the riches of its medical literature.*

I remain, Sir,
Yours faithfully,
May 29, 1851. Θεραπευτικος.

PROVINCIAL MEDICAL COLLEGIATE INSTITUTION.

To the Editor of the Provincial Medical and Surgical Journal.

Sir,—I am obliged by your notice of my proposed scheme of preliminary instruction for youths intended for the medical profession. I have been applied to by several for the terms upon which such a course could be afforded. My long experience in providing for large numbers has made me pretty well acquainted with the economy of the school room and the household, and the cost at which each can be suitably maintained.

A gentlemanly education, if necessary to any, is certainly most necessary to members of the medical profession. But a gentlemanly education can only be secured by surrounding pupils with those habits and associations that produce gentlemanly feelings and a gentlemanly bearing. The pupils must be taught by gentlemen, and must be treated as gentlemen. This cannot be done without considerable expense. Masters, servants, and domestic arrangements, to conduce to such an end, are costly. A liberal and a gentlemanly education cannot be secured at a very low rate. Either inferior arrangements in all those departments must be adopted, or the establishment must be aided by endow-

ments, (public or private,) if only a small charge be made for each pupil. Should I be admitted to an audience of the Association at their next annual meeting, I think I shall be able to show them at how small a cost such an institution can be efficiently maintained, to afford a liberal education and liberal treatment, in addition to a sound, moral, and religious training.

If the Association were to raise money sufficient to build, and completely furnish, a school for a hundred resident pupils and masters, I do not think even then they could fix a less *inclusive* sum than £45 as the annual payment.

It will give me pleasure to afford the Association assistance in any way they may be pleased to accept. If under their patronage and control, *but at my risk*, I will consent that the terms at Tarvin Hall shall not exceed fifty guineas per annum, *all charges included.* If they think well to make the concern their own, I will use my utmost exertions to raise funds for that object, and will gladly conduct it for them as their salaried officer.

With a well-established and flourishing institution at present in my hands, I can have no other object in view in making these offers than the filling up of an educational gap that has long been observed, and by the profession at large admitted, to exist. Already much time has been lost, and many unavailing efforts have been attempted, I shall, therefore, at once make arrangements to receive some twenty or thirty additional pupils after the Midsummer vacation, to form the nucleus of a medical class, and have already secured the assistance of one professional gentleman for that purpose. My terms I forward herewith for insertion in your advertising columns, subject to the reductions under the conditions suggested above.

I am, Sir,
Your obliged and faithful servant,
JOHN BRINDLEY.

Medical Intelligence.

DINNER TO SIR C. M. CLARKE.

On Tuesday, May 27, about 160 medical men attended the dinner at Willis's Rooms, given by them to Sir Charles M. Clarke, in testimony of their respect and regard. The day was selected as being the anniversary of his birth. Sir Henry Bishop conducted the musical arrangements, and presided at the pianoforte, and some eminent male and female vocalists contributed signally to the amusements. Amongst other songs, was an appropriate one written expressly for the occasion, by Dr. Badeley. Sir B. Brodie was in the chair, and the party did not separate until a late hour.

FOREIGN CLIMATES.

Amongst the erroneons opinions still prevalent in this country respecting the so-called salubrity of foreign regions over that of England, the ideal superiority of the south of France occupies a prominent position in the minds of some individuals. This tendency to migrate southward is shown by the number of invalids who there pass the winter in expectation of finding an Elysium, redolent of comfort, health, and happiness. How far such notions ultimately become realized, may be illustrated, in addition to other evidence, by the subjoined observations recently written to a friend in London, by a lady resident at Pau the whole of last season, to which place she had come for the *benefit* of her health.

Extract of a letter from Pau.—"The air here is so relaxing and enervating, that one feels constant heaviness and depression of spirits, together with headaches and languor. One is not fit for much mental exertion; and a clergyman told me he could only write one sermon per week, whereas in Switzerland he could compose two with great ease. Oh, what I would give for a 'blowy day!' Another most uncomfortable circumstance is the difficulty we have in getting any medical prescription made up, and we are obliged to send to England to have ours properly mixed and accurately composed."

The above report is by no means encouraging, nevertheless, many persons, like a flock of sheep jumping over a fence into a quagmire, often follow each other without inquiring why or wherefore, but merely from the blind confidence they have in their leader. Alas, will ignorance never be dispelled?—(From a Correspondent.)—*Lancet.*

NICOTINE.

An extraordinary trial is now going on in Belgium; the accused, the Viscount and Viscountess Bocarme, being charged with the murder of the Viscountess' brother by nicotine. The Viscount, who is in embarrassed circumstances, had for some time past addicted himself to the study of vegetable chemistry, and, as he himself acknowledged, had obtained several phials full of nicotine. The contents of one of these, the Viscountess asserts, he forced into his brother-in-law's mouth, and thus produced instant death.

NAVAL APPOINTMENTS.

Surgeon John Gibson (1835) to be Surgeon Superindent of the *Minden* convict-ship. Surgeon John Smith, (*c.* 1830,) from the *Impregnable* flag-ship at Devonport, to the *Blenheim* convict-ship.

ROYAL COLLEGE OF SURGEONS.

The following gentlemen were admitted members on Friday, the 23rd ult. :—James Joseph Roosmale Cocq, Ceylon; James Couch, Swansea, South Wales; Chas. Dudley Kingsford, Wellington Street, Southwark; Thomas Odell, London; Wm. James Shone, Bangor, North Wales; Wm. Harris Stretton, Leicester; Geo. Edward Webster, Cambridge.

SOCIETY OF APOTHECARIES.

Gentlemen admitted members on Thursday, the 22nd ult. :—Alfred Carpenter, Rothwell, Northamptonshire; Henry Joseph Herschell Griesbach, Millington, Yorkshire; Francis Martin, Brighton; Henry Thompson, Croydon; Edward Wilmhurst Tait, Heytesbury, Wilts.

The following gentlemen were also admitted members on Thursday, the 29th ult. :—Francis Ayrton, Liverpool; Edward Somerset Cleveland, Madras; George Henry Edwards, Royal Navy; Thos. Lowney Ridley, Newcastle-on-Tyne; Charles Rothwell, Bolton-le-Moors; George Edmund Smale, Plymouth.

THE COLLEGE COUNCIL.

As the time approaches when the Fellows of the Royal College of Surgeons may expect to be called together, to elect from among themselves gentlemen to occupy the vacant seats in the council-chamber occasioned by the resignations of John Painter Vincent and Edward Cutler, Esqrs., we consider it may be acceptable to a large number of our readers to publish, from the chronological list of Fellows, the first dozen names of gentlemen enjoying that distinction, who are elegible for election into the Council :—The first on the list is Gulliver, George, Esq., F.R.S., Brompton, Surgeon to the Royal Horse Guards, Blue; Tuson, Edward Wm., Esq., F.R.S., Harley Street, Cavendish Square; Owen, Richard, Esq., F.R.S., Royal College of Surgeons; Coulson, William, Esq., Frederick Place, Old Jewry, Senior Surgeon to St. Mary's and Magdalene Hospitals, and Consulting Surgeon to the German and City of London Lying-in Hospitals; Dalrymple, John, Esq., F.R.S., Grosvenor Street, Consulting Surgeon to the Royal Ophthalmic Hospital and to the North London Infirmary; Partridge, Richard, Esq., F.R.S., New Street, Spring Gardens, Surgeon to King's College Hospital and Professor of Anatomy; Hilton, John, Esq., F.R.S., New Broad Street, Surgeon to Guy's Hospital, and Lecturer on Anatomy; Quain, Richard, Esq., F.R.S., Cavendish Square, Surgeon, University College Hospital, and Professor of Clinical Surgery in the University; Cock, Edward, Esq., Surgeon to Guy's Hospital, and Consulting Surgeon to the Asylum for the Deaf and Dumb; Solly, Samuel, Esq., F.R.S., St. Helen's Place, Assistant Surgeon, and Lecturer on Clinical Surgery at St. Thomas's Hospital; Tatum, Thomas, Esq., George Street, Hanover Square, Surgeon to St. George's Hospital, and Lecturer on Surgery; Shaw, Alexander, Esq., Henrietta Street, Cavendish Square, Surgeon to the Middlesex Hospital, and Lecturer on Surgery.—The above list of twelve Fellows is exclusive of those gentlemen residing in the provinces, who from that circumstance are ineligible for a seat in the Council.

OBITUARY.

Mr. Richard Phillips, F.R.S.L. & E.

We regret to have to announce the death of the above-named distinguished chemist and pharmaceutist, who departed this life at Cambridge, on the 11th of May, in his 73rd year, after a few days' illness.

Mr. Phillips was appointed Lecturer on Chemistry to the London Hospital in 1817, and was afterwards Professor of Chemistry at the Military College, Sandhurst. He held for several years the Chemical Lectureship at Grainger's Medical School, in the Borough; and subsequently a similar appointment at St. Thomas's Hospital. In 1839 he was appointed to the offices of Curator and Chemist to the Museum of Practical Geology, now in Jermyn Street, which was opened by His Royal Highness Prince Albert on the day following the death of the subject of this sketch.

The notice of the scientific world was first attracted towards Mr. Phillips by his "Analyses of the Bath Waters," in 1805, which elaborate paper was rapidly followed by several others upon various mineral waters and rare minerals, published in the various scientific serials of that period. In 1822 Mr. Phillips was elected a Fellow of the Royal Society of London; and about this time published a paper in their "Transactions," in conjunction with Dr. Faraday, which distinguished philosopher he had the honour of introducing to that learned Society.
